Do Children of Immigrants Make Differential Use of
Public Health Insurance?

Do Children of Immigrants Make Differential Use of Public Health Insurance?

Abstract

Recent changes to federal law will sharply reduce the eligibility of immigrant children for Medicaid, the main system of public health insurance for poor women and children. Although these changes are likely to reduce Medicaid coverage among immigrants, it is difficult to predict their effects on either health care costs or public health because these more important outcomes are determined by utilization of care rather than by insurance coverage per se. Medicaid differs in a fundamental way from other welfare programs, because it is possible for uncovered individuals to receive acute care which is paid for by the program ex post. The new laws will not affect the eligibility of immigrant children for these emergency medical services.

This paper presents evidence from the U.S. National Health Interview Survey about the relationship between eligibility, coverage, and utilization of care. These effects are identified using recent expansions of Medicaid eligibility to previously ineligible groups of children. The results suggest first that increases in Medicaid eligibility led to greater increases in Medicaid coverage among children of the native born than among children of immigrants. However, a second finding is that one cannot use changes in patterns of coverage to make inferences about changes in patterns of utilization. Increases in Medicaid eligibility were associated with increases in the probability of having received routine care among both immigrants and natives, while the number of hospitalizations rose only among natives. The evidence suggests then that the new laws making immigrant children ineligible for Medicaid coverage are likely to reduce the use of relatively low-cost routine preventive care, without having much impact on the utilization of more costly hospital care.
The fraction of the U.S. population that is foreign born has risen dramatically over the past two decades from 4.7% in 1970 to 7.9% in 1990 (Banister, 1994). First and second-generation children of immigrants are the fastest-growing segment of the U.S. population under age 15 -- by 2010, it is estimated that 20% of school-aged children will be children of recent immigrants (Lamberg, 1996). By 1997, one in every 6 children (12 million) were immigrants or had immigrant parents (Hernandez and Charney, 1998).

The increased inflow of immigrants has been accompanied by growing concern about the cost of social services used by immigrants and their families. Many previous studies have shown that because immigrants tend to be poorer than the native born, their children are more likely to be eligible for welfare programs (Blau, 1984; Borjas, 1990; Borjas and Hilton, 1996; Jensen, 1988; Tienda and Jensen, 1986; Trejo, 1992). Concern about the fiscal burden imposed by immigrants provided the impetus for certain provisions of the passage of the Personal Responsibility and Work Opportunity Reconciliation Act of 1996 (P.L. 104-193). This bill will sharply curtail the availability of welfare benefits for immigrants. It is estimated that of the projected $56 billion in federal funds the law will save over the next 6 years, almost half will come from a reduction of payments to immigrants (Fix and Zimmerman, 1997).

Medicaid, a system of public health insurance for poor women and children, is one of the more costly social programs available to the families of immigrants. In recent years, the U.S. spent about $3.4 billion annually on cash welfare payments to children under the Aid to Families with Dependent Children program (Clark, 1994), and $5.5 billion on payments to children of immigrants under the
Medicaid program.¹ The new law will ban legal immigrants from Medicaid for 5 years after their arrival in the U.S., after which states will have the authority to decide whether or not they will be eligible. Undocumented immigrants have never been eligible for coverage of routine care under the Medicaid program. All immigrants will continue to be eligible for coverage of emergency medical care, and for public health assistance (immunizations and treatment of communicable diseases). Refugees and citizen children of immigrants will also remain eligible for Medicaid coverage.

Although the law is likely to reduce Medicaid coverage, it is difficult to predict the effect it will have on either health care costs or public health because these more important outcomes are determined by utilization of care rather than by insurance coverage per se. Medicaid differs in a fundamental way from other welfare programs, because it is possible for uncovered individuals to receive emergency services which are paid for by the program ex poste (while it is not possible for example, for someone ineligible for cash assistance to legally receive cash benefits). The evidence presented in this paper is consistent with the previous evidence that because of their characteristics, immigrants are more likely than non-immigrants to be eligible for Medicaid. However, it suggests that making children ineligible for Medicaid coverage will reduce the use of relatively low-cost routine preventive care, without having much impact on the utilization of more costly services.

The rest of the paper is laid out as follows: Necessary background information about the Medicaid program and a discussion of its effects on the incentives facing eligible immigrants and non-

¹ By way of comparison, the entire budget for AFDC was approximately 22 billion annually. AFDC has recently been replaced with the Temporary Aid for Needy Families program (TANF). According to Clark (1994) Medicaid expenditures for immigrants total 16.6 billion dollars. Since two-thirds of Medicaid expenditures are on the elderly, this implies that 5.5 billion is spent on children.
immigrants is given in Section I. Section II outlines the instrumental variables strategy. The data is described in Section III. Section IV provides the empirical results while Section V concludes.

I. The Medicaid Expansions and Incentives for Immigrants and Non-Immigrants

Historically, eligibility for Medicaid was closely tied to the receipt of cash welfare payments under the Aid to Families with Dependent Children program. Hence, eligibility was effectively limited to very low income women and children in single parent families. Beginning in 1984, states were first permitted and then required to extend Medicaid coverage to other groups of children. By 1992, states were required to cover children below age 6 in families with incomes up to 133% of the federal poverty line, and children between ages 6 and 19 with family incomes up to 100% of the poverty line; states also had the option of covering infants up to 185% of the poverty line. A list of the relevant statutes is given in Appendix Table 1.

The important point to note is that states took up these options at different rates, so that there was a great deal of variation across states in both the income thresholds and the age limits governing Medicaid eligibility. Appendix Table 2 shows the maximum age covered by Medicaid in each state at three different points in time, as well as the maximum income limit that applied to any child made eligible by the expansions (the oldest child eligible was generally subject to a less generous income cutoff). Older children remained eligible if their families received AFDC. The table shows that as of January 1988, 26 states had taken advantage of the options described above to extend Medicaid

---

2 States received federal matching funds for coverage of these groups. However, some states have extended coverage to children above 200% of the poverty line, using state only funds.
eligibility to previously ineligible children. By December 1989, all 50 states had expanded Medicaid eligibility—however states like Colorado covered only infants in families with incomes up to 75% of the poverty line, while more generous states, like California, covered children up to age 5 in families with incomes up to 100% of poverty, and covered infants in families with incomes up to 185% of the poverty line.

By December 1991, most states had been required by the federal government to increase the age limits and income limits still further. Table 1 illustrates the growing uniformity in the way that children were treated in three states which began the period with widely differing eligibility criterion: California, Texas, and New Jersey. This variation in eligibility thresholds by state, year, and age of child will be exploited to identify the effects of Medicaid eligibility.

A large literature documents the fact that eligible individuals do not always take up public assistance— for example, only about two thirds of those eligible for AFDC or Unemployment Insurance receive benefits (Blank and Card, 1991; Blank and Ruggles, 1993). The probability of taking up benefits should be systematically related to the relative costs and benefits of being covered. For example, as Blank and Card suggest, those who expect to be unemployed for only a short spell may be less likely to apply for or receive benefits. The available pre-expansion evidence suggests that although takeup of Medicaid among children on AFDC is high, only about one quarter of children eligible through other aspects of the program (e.g. under the Ribicoff provisions) took up coverage (Shore-Sheppard, 1996).

It is not unreasonable to suppose that immigrant parents face higher costs of enrolling their children in the Medicaid program than non-immigrants. First, the General Accounting Office (GAO,
1994) reports that many applications are denied, and that half of all denials occur because the applicant failed to supply supporting documentation (such as birth certificates or pay stubs), or failed to keep all of the necessary appointments. It may be more difficult for immigrants to follow these procedures. Second, although citizen children are eligible for all Medicaid services, and even undocumented children are eligible for emergency services under the Medicaid program, immigrant parents may fear harassment by authorities, particularly if they or other family members are themselves undocumented. Third, the residential segregation of many immigrants may make it difficult to get to an enrollment center. Fourth, language barriers may make the enrollment process more difficult.

It is also possible that the benefits of formal enrollment are not as great as they might at first appear, because it is often possible for eligible children to obtain acute services even if they are not formally covered at the time that services are rendered. The GAO gives the following example: "The child of a single, uninsured, working mother incurred a $20,000 hospital bill... The hospital referred this case to an enrollment vendor firm after determining that it was a potential Medicaid case. After contacting the mother, the firm initiated and submitted a Medicaid application. The firm gave the applicant a list of verification items she would have to provide. However, the applicant did not provide the requested items and Medicaid coverage was denied. Upon learning of the denial, the firm contacted the applicant twice weekly for a period of 2 months to get her to cooperate... Eventually, the applicant responded and submitted the verification items and a signed power of attorney to the firm... The signed power of attorney allowed the firm to appeal the denial successfully” (pg. 24, 1994). In this example, the child became covered by Medicaid for a time. But eligibility must be periodically re-established in order to retain coverage, and one suspects that this child's coverage might have been
particularly likely to lapse subsequently.

Hence, immigrant parents with an eligible child have two options: They can choose to incur the transactions costs and become covered. The Medicaid program will then cover the costs of both preventive care and acute care for their child. Alternatively, they may choose to forego the transactions costs and remain uncovered, knowing that acute care will be provided under the Medicaid program as necessary. Viewed in a dynamic context, parents who face higher transactions costs may simply choose to enroll their children less often than other parents. For example, instead of keeping children continuously enrolled, which requires going through an administrative procedure at least every 6 months, they might choose to enroll their children only when they needed to take them to the doctor for some form of routine care.

The role of transactions costs is depicted in Figure 1, which shows the tradeoff between expenditures on health insurance for children and expenditures on other child goods. An eligible child whose family faces no transactions costs becomes covered by the program and is able to consume at point M1. A family facing high transactions costs can choose to become enrolled and consume at point M4, or it can choose to forego coverage, and consume slightly less health insurance at point M2. Thus, if parents have preferences like those depicted in the figure and immigrant parents face higher transactions costs than non-immigrant parents, then their eligible children will be less likely to become formally covered.

Parents of eligible children may also have another decision to make: Whether or not to take up Medicaid coverage for their children and drop the child’s private health insurance coverage. Cutler and Gruber (1996) emphasize that public insurance could “crowd-out” private insurance in this way.
Alternatively, they point out that employers might stop offering private insurance of employees’ dependents if substantial numbers of them were to become covered under public programs. Immigrant parents may be more likely than non-immigrants to work for small low-wage employers who offer insurance at less favorable rates than large employers, or who do not offer it at all.

This situation is illustrated in Figure 2, in which immigrant parents are assumed to face a flatter tradeoff between health insurance for their children and other child goods than other parents. Given these opportunities, immigrant parents will consume less child health insurance than non-immigrant parents in the absence of Medicaid eligibility (compare point A to point B). Now consider what happens when the child becomes Medicaid eligible, assuming that the transactions costs associated with becoming covered are similar to those described in Figure 1. Native-born parents with the preferences shown in Figure 2 do not change their insurance arrangements: The private insurance they are purchasing is far superior to what is available under Medicaid. Immigrant parents on the other hand, are made better off by moving to M2 (eligible but not covered). Although the health insurance offered at M2 is inferior to what was being purchased previously, the cost savings allow a more than offsetting increase in the consumption of other child goods. In the data, a movement from A to M2 will appear as an increase in the fraction of children who are uninsured.

These diagrams implicitly assume that being eligible for Medicaid coverage of acute services is better than not being insured at all (i.e. that point M2 is higher than point N). Since some emergency care is likely to be available to all children in the United States, one may question this assumption. However, there is considerable evidence which suggests that hospitals are able to determine relatively quickly whether someone is likely to be Medicaid eligible. For example, Piper et al. (1990) found that
a 1985 expansion of Medicaid eligibility to married pregnant women in Tennessee increased Medicaid enrollments, but that most of this increase is likely to have occurred at the time of the delivery. And it is well known that insured patients receive more intensive treatment than uninsured patients along a number of margins (c.f. Hadley et al. (1991), Wenneker et al. (1990), and Currie and Gruber (1997)). Hence, it seems likely that patients who are eligible for Medicaid will receive better care (and receive it with greater certainty) than those who are not, even if the later do receive some acute care.

In summary, these diagrams suggest that if immigrant parents face differences in transactions costs and/or opportunities relative to native-born parents, then they will make different choices about health insurance. Among parents who were not purchasing private health insurance for their children previously, increases in Medicaid eligibility will be associated with larger increases in formal coverage among children of the native-born than among children of immigrants. And among parents who were purchasing private health insurance to begin with, increases in eligibility for Medicaid will be more likely to cause “crowd-out” among immigrants than among non-immigrants. 3

It is more difficult to make predictions about the relationship between utilization and eligibility among immigrants and non-immigrants. If eligible children of immigrants are less likely to be formally covered than children of non-immigrants, then utilization of non-acute services is less likely to be paid for by Medicaid. On the other hand, if the main difference between immigrants and non-immigrants is

---

3 Both diagrams illustrate the fact that even if the child is not formally covered, the family may be made better off when the child becomes Medicaid eligible. Since the utilization of medical care given health status is known to be a normal good, one would expect some of this increase in household “income” to translate into an increase in the number of visits. However, it is difficult to judge how large this income effect should be given measurement error in income and the fact that we do not know the value of Medicaid eligibility to the family.
that the later are less likely to be continuously covered, we might see little difference in the utilization of routine care because immigrants may simply bunch care during periods when they are covered. In the case of hospitalizations, eligibility is arguably a more important determinant than coverage given that a hospital that treats an eligible but uncovered child can receive reimbursement from Medicaid *ex post facto*.

Although the preceding discussion assumes that immigrant and native-born parents have similar preferences, it is possible that there are systematic cultural differences in attitudes towards the utilization of medical care. For example, eligible immigrant parents might be less likely to enroll in Medicaid because they value the available services less than native-born parents. It is also possible that immigrant parents have less information about these programs -- Currie and Gruber (1996) conclude that lack of information about welfare programs among the working poor may be an important barrier to takeup of coverage. However, as we shall see, such cultural or informational explanations are not particularly consistent with the findings of this study: Children of immigrant parents actually show larger changes in the utilization of basic medical care when they become Medicaid-eligible than children of the native-born.

**II: Methods**

The main empirical problem involved in investigating the effects of Medicaid eligibility on coverage and utilization is that those children who are most likely to be eligible, are least likely to take up coverage or to use services, given health status. They are also more likely to be ill. Currie and Gruber (1996b) describe the construction of a detailed simulation model that uses information about
state rules, the child's age, and family characteristics to impute individual Medicaid eligibility.\textsuperscript{4} They estimate that between 1989 and 1992 the fraction of children less than 15 years of age who were eligible for Medicaid increased from 20.4% to 31.2%, and that all but 2.1 percentage points of this increase can be attributed to changes in state Medicaid rules as opposed to changes in economic conditions or demographics.

In what follows, the Currie-Gruber imputation program is used to determine individual eligibility. This measure is included in linear probability models of health insurance coverage and the utilization of medical care below. However, these Ordinary Least Squares (OLS) estimates are subject to two sources of bias. The first is omitted variables bias. In addition to eligibility, all of the models include observable variables associated with Medicaid eligibility such as: the absence of a male head, income, the number of children in the family, and the age of the child (through single year of age dummies). Family income and the child's gender, race, and ethnicity, whether he or she is the oldest child, the number of siblings, the education of the mother and (if present) the father, whether the mother or father was the respondent, the presence of other adult relatives, and whether the family lives in a central city or rural area are also controlled for.

Even after conditioning on this detailed set of controls, however, persons who are eligible for Medicaid may have other characteristics that make them less likely to take up Medicaid coverage or to

\textsuperscript{4} They use data from the National Health Interview Survey and Current Population Survey. In these data sets, it is necessary to impute eligibility at the time of the survey on the basis of annual income. Devine and Heckman (1994) conduct a comparison of eligibility simulations using the CPS to some constructed using the Survey of Income and Program Participation (SIPP), which has monthly income data. They conclude that CPS-based simulations of eligibility for training programs produce estimates remarkable similar to those using the SIPP.
utilize medical care. For example, they may be more likely to live in areas with limited access to physicians (c.f. Fossett, 1992; Fossett and Peterson, 1989). In this case, OLS estimates of the effects of eligibility on coverage and utilization would be biased towards zero. If these omitted factors are more important for immigrants than for non-immigrants, then estimates for immigrants may be more severely affected by these biases than estimates for non-immigrants.

The second problem is that there may be substantial measurement error in the eligibility indicator, given limitations of the NHIS income data that are discussed below. Such measurement error would normally be expected to bias the estimated effect of eligibility towards zero. Since Medicaid coverage is also self-reported (with some verification of the holding of Medicaid cards by interviewers), it may also be measured with error. An additional measurement problem is that children of immigrants who are themselves undocumented are ineligible for Medicaid coverage of non-emergency services, and it is not possible to identify these children.⁵

Hence, in addition to the OLS estimates, instrumental variables estimates are presented below. The aim of the instrumental variables procedure is to abstract from characteristics of the child and/or family that may be correlated with eligibility, survey response error, and the dependent variables, and to achieve identification using only legislative variation in Medicaid policy. One way to do this would be to instrument imputed individual eligibility in the NHIS using the fraction of children in the same state, year, and age who are eligible, calculated using the Current Population Survey (CPS). This instrument

---

⁵ It is difficult to estimate the fraction of children of immigrants who are themselves undocumented. Estimates based on the 1990 Census suggest that 3 in 20 immigrants are undocumented (Banister, 1994). However, many undocumented adult immigrants have citizen children who are entitled to services under the Medicaid program. It is also unclear that the undocumented are accurately counted in a survey such as the NHIS.
would capture differences in Medicaid eligibility across states, years, and age groups, and would purge the regression of individual-level sources of variation in eligibility.

This approach would run into two problems in practice, however. First the CPS is simply not large enough to permit reliable estimation of the fraction of children eligible in each state, year, and age category. Second, these estimates could be biased by the omission of characteristics of state, year, and age groups that are correlated with both the fraction eligible and with utilization or health. For example, if infants in a given state and year were particularly poor they might have both higher eligibility levels and fewer doctor's visits, resulting in a downward bias in estimates of the effects of eligibility on utilization.

In order to address these problems, an instrument that varies only with the legislative environment, and not with its economic or demographic conditions was developed. This instrument was constructed by first selecting a national random sample of 300 children for each single year of age (0 to 14) from the CPS, in each year, and then using the Currie-Gruber program to calculate the fraction of this national sample of children who would have been eligible for Medicaid in each state and year. This measure can be thought of as a convenient summary of the legislation affecting the Medicaid eligibility of children in each state, year, and age group. In what follows, we use linear probability models for ease of computation and for consistency of this instrumental variables procedure (Heckman and MaCurdy, 1985).

That is, how many of the 300 one year olds would be eligible if they all lived in California, how many would be eligible if they all lived in Massachusetts, etc.? The sample size of 300 was chosen due to data and computational constraints. In order to assess the severity of potential problems due to sampling variability, the instrument was constructed twice, using two different random samples. The correlation between the two instruments was 0.97.
In principle, this instrumental variables strategy overcomes the econometric difficulties noted above -- the model is purged of endogeneity bias and of biases due to individual-level omitted variables that are correlated with both eligibility and outcomes. To the extent that the measurement error in the instrument is uncorrelated with the measurement error in the individual eligibility measure, this procedure also surmounts the measurement error problem. Finally, using a national random sample eliminates the effects of state and year specific economic conditions that might be correlated with both eligibility and with utilization; the problem of small age/year/state cell sizes is also eliminated. This instrument is strongly correlated with individual eligibility, among both natives and immigrants -- the T-statistic is over 10 in the first stage equations.

Of course, using legislation as the source of identifying variation raises the question of whether laws can be treated as exogenous variables. It is possible, for example, that states raise eligibility for Medicaid in response to poor outcomes among children. It is important to note that much of the identifying variation used in this paper is a result of federal mandates, and therefore outside the control of state governments. States differed widely in their propensity to take up optional Medicaid expansions prior to 1989. Hence states started with differing levels of generosity, a fact that can be controlled for by including state fixed effects in the empirical model. Between 1989 and 1992, however, even the most recalcitrant states were forced to extend Medicaid coverage to meet federal standards, with the result that greater uniformity across states was achieved. Thus, although New Hampshire and Minnesota ended up with similar programs in 1992, New Hampshire expanded

---

7 If the measurement error stems mainly from random individual response error, then measurement error in the CPS instrument will be uncorrelated with that in the NHIS data, especially given the fact that the measure calculated using the CPS is the average eligibility for a large group.
eligibility much more rapidly over this period as federal mandates began to bite. Note that possible legislative endogeneity would be a potentially far greater problem if, instead of simulating the fraction eligible for Medicaid, various state rules that help to determine eligibility such as maximum AFDC benefit levels had been used. The problem is that benefit levels in other programs may be correlated with other characteristics of states that affect the utilization of health care and insurance coverage.

The models estimated in this paper all take the following form:

$$\text{(1) OUTCOME} = \beta_0 + \beta_1 \text{ELIG} + \beta_2 \text{PARIMMIG} + \beta_3 \text{PARELIG} + \beta_4 \text{X} + \beta_5 \text{STATE} + \beta_6 \text{YEAR} + \beta_7 \text{CHILDAGE} + \beta_8 \text{AGEYEAR} + \beta_9 \text{STATEAGE} + \epsilon,$$

where OUTCOME is an indicator for either insurance status or utilization, ELIG is an indicator equal to one if the child is eligible for Medicaid, PARIMMIG is an indicator equal to one if at least one parent is an immigrant, PARELIG is an interaction term equal to one if the child is eligible and a parent is an immigrant, and X is a vector of additional explanatory variables. In addition, the models all include state fixed effects and a full set of dummy variables for calendar years, and for each child’s single year of age. These variables control for variables such as secular trends in utilization rates, or changes in the recommended schedule of visits for various age groups. Interactions between 5 broad age groups and the year dummies, and between the 5 age groups and the state of residence are also included.\(^8\)

\(^8\) The five groups are: less than 1; greater than or equal to 2 and less than or equal to 4; greater than or equal to 5 and less than or equal to 7; greater than or equal to 8 and less than or equal to 10; and greater than or equal to 11. All the children in the sample are 14 or under.
In this framework, we can test for whether eligible immigrants behave similarly to eligible natives by looking at whether \((\beta_1 + \beta_2 + \beta_3 = \beta_1)\). In principal, it would be possible to estimate a fully interacted model in which all of the coefficients were allowed to vary with immigrant status. In practice, it was found that this had little effect on the inferences that could be drawn from OLS estimates of the effects of eligibility. However, the TSLS estimates were much less precisely estimated in the fully interacted model, which may reflect the difficulties involved in trying to draw many inferences about differences between immigrants and natives from a relatively small sample of immigrants.

III. Data

The National Health Interview Survey (NHIS) interviews a large, nationally representative cross-section of American families each year.\(^9\) The baseline survey collects information about demographic characteristics and family income. There are also a number of questions about the utilization of medical care over the previous year. These data cover approximately 100,000 individuals and 30,000 children less than 15 in each year. This age cutoff was chosen in order to avoid issues arising from the fact that teens may become eligible for Medicaid due to pregnancy.

Beginning in 1989, the NHIS has asked all non-native-born adults in the household how long they have lived in the U.S. Using this information it is possible to determine whether either the mother

\(^9\) The models estimated in this paper are unweighted, but include controls for key variables used in stratifying the sample such as race, central city residence, and rural residence. The inclusion of these variables results in estimates similar to those that would be obtained by weighting (Dumouchel and Duncan, 1983).
or father of the child is an immigrant\textsuperscript{10}. The relatively few respondents who answer that they "don't know" how long they have been in the U.S. are also treated as immigrants. Sixteen percent of the sample children have at least one parent who is an immigrant.

The NHIS fields supplements that ask additional questions about health insurance status every three years. Insurance supplements were fielded in 1989 and 1992, years that neatly bracket much of the increase in Medicaid eligibility for low income children. Using these supplements, it is possible to determine whether the child was covered by private insurance, Medicaid, or was uninsured at the time of the interview.\textsuperscript{11}

Information from the main NHIS survey can be used to impute Medicaid eligibility to each sample member. The questions about private health insurance coverage and no insurance coverage are straightforward. The 1989 insurance supplement asks four questions asked about public health insurance coverage. Parents are asked whether each child received Medicaid in the past 12 months, has a Medicaid card, is covered by some other type of public assistance program that pays for health care, or is covered by any type of public assistance health insurance coverage. In 1989 for example, 7287 respondents reported receiving Medicaid in the past 12 months, 7319 said they had a Medicaid card (and this was verified for 4534 individuals), 8072 said that they were covered by public assistance health insurance coverage, and 686 said that they were covered by some form of public assistance health insurance coverage other than Medicaid. Hence, the most inclusive definition of Medicaid coverage, which is the one adopted here, is to count anyone who received public assistance health insurance that was not of some "other" type as Medicaid covered. This leaves 7386 individuals which is not very different than what would be obtained using the least inclusive measure -- the 7287 individuals who reported "receiving" Medicaid in 1989. Experimentation with other possible measures of Medicaid coverage produced results similar to those reported below. The 1992 supplement simply asks about Medicaid coverage. The existence of "other" public health insurance programs accounts for the fact that the effects of eligibility on Medicaid coverage, private health insurance coverage, and no insurance coverage may not sum to zero.

\textsuperscript{10} In principal, one could distinguish between the effects of having an immigrant father and the effects of having an immigrant mother. However, 83\% of children who had at least one immigrant parent had a mother who was an immigrant, while 70\% of these children had an immigrant father. Thus, there is a high degree of correlation between the two measures, and it proved impossible to separate these effects.

\textsuperscript{11} The questions about private health insurance coverage and no insurance coverage are straightforward. The 1989 insurance supplement asks four questions asked about public health insurance coverage. Parents are asked whether each child received Medicaid in the past 12 months, has a Medicaid card, is covered by some other type of public assistance program that pays for health care, or is covered by any type of public assistance health insurance coverage. In 1989 for example, 7287 respondents reported receiving Medicaid in the past 12 months, 7319 said they had a Medicaid card (and this was verified for 4534 individuals), 8072 said that they were covered by public assistance health insurance coverage, and 686 said that they were covered by some form of public assistance health insurance coverage other than Medicaid. Hence, the most inclusive definition of Medicaid coverage, which is the one adopted here, is to count anyone who received public assistance health insurance that was not of some "other" type as Medicaid covered. This leaves 7386 individuals which is not very different than what would be obtained using the least inclusive measure -- the 7287 individuals who reported "receiving" Medicaid in 1989. Experimentation with other possible measures of Medicaid coverage produced results similar to those reported below. The 1992 supplement simply asks about Medicaid coverage. The existence of "other" public health insurance programs accounts for the fact that the effects of eligibility on Medicaid coverage, private health insurance coverage, and no insurance coverage may not sum to zero.
child, although there are several problems to be overcome. First, family income is missing for a number of households, as shown in Appendix Table 3. Missing income data is imputed by using CPS data to estimate regressions of income on household characteristics, and then using the regression coefficients to calculate income for NHIS households with similar characteristics. The Census bureau uses a similar procedure to impute missing data in the CPS. These estimates were calculated separately for each year.\footnote{For most of the missing observations, we know whether income was greater than or less than $20,000, so I can impute income within those subsamples. The imputation regressions fit fairly well; the R-squareds for the yearly regressions estimated using all individuals average 0.45. For those with incomes below $20,000, the R-squareds average 0.32; while for those with incomes above $20,000, the R-squareds average 0.25.}

Second, when family income is reported, it is reported in brackets. This is less of a problem than it might first appear because it causes problems only when the Medicaid cutoff falls in the middle of the family's reported income bracket, and the income brackets are in $1000 increments if income is less than $20,000.\footnote{For incomes over $20,000 and less than $50,000 the brackets are in increments of $5,000. The last bracket is for incomes over $50,000.} Two approaches to this problem were tried. The first involved predicting income within the bracket using regressions estimated using the CPS, as described above. The second method involved choosing a random number within the bracket. Since the estimated fraction eligible was very similar under both approaches, the simpler method was used. The estimated models control for income brackets rather than the noisy imputed income measure, and interactions between the (nominal) income brackets and the year dummies are included in order to account for inflation. The omitted income category in all the models estimated below is "missing".
A third problem is that there is no information about the distribution of income across family members, or about income sources. This lack of information is potentially problematic because, for example, some portion of earnings, but not other types of income, can be disregarded from total family income in determining AFDC eligibility, which in turn affects Medicaid eligibility. In this paper, these disregards are applied to total income, under the assumption that most family income comes from earnings, especially in poor families. These limitations of the NHIS income data do not seem to lead to any systematic measurement problems; the resulting annual eligibility rate in the NHIS is similar to that calculated using the CPS in terms of both levels and the time series trend.

This paper focuses on three measures of the utilization of medical services over the past year: Whether or not the child had a doctor visit in the last year; the number of doctor visits if the child had any visits; and whether or not the child was hospitalized in the past year. Since the utilization measures are available in every year, the data set available for examining utilization is approximately twice as large as that available for examining insurance coverage.

Pediatric guidelines recommend at least one doctor's visit per year for all of the children in the sample, so that the absence of a doctor's visit in the previous year is suggestive of an access problem, regardless of underlying morbidity. If the marginal benefit of doctor's visits is decreasing in the number

---

14 In the 1984 CPS, 75% of the average child's family income comes from his or her parents' earnings.

15 In the years 1989 to 1992, the fraction of children eligible for Medicaid in the NHIS data was 19.3, 25.2, 27.5, and 31.5%. These numbers are very close to those calculated from the CPS.

16 Although the NHIS asks many other questions about utilization, most pertain to a two week window. Even in a sample as large as the NHIS, this sampling scheme yields very small samples of immigrant children who have received specific services.
of visits (which seems reasonable if children who get any visits receive some necessary preventive care), then this first visit is also the most important from the point of view of the child's health. Nevertheless, it is interesting to examine the number of doctor's visits conditional on the child receiving care, since the cost of care will be increasing in the number of visits. Because this distribution is highly skewed to the right, the analysis focuses on the log of the number of doctor's visits.

We examine hospitalizations primarily because they are so much more expensive than doctor's visits, and hence account for a disproportionate share of Medicaid costs. For example, the U.S. House of Representatives (1993) reports that in 1991, the Medicaid program spent $5.4 billion on inpatient hospital services for AFDC children, and only $1.5 billion on physician services. However, approximately 80% of children receive a doctor's visit in any given year, while only 3 to 5% of children are hospitalized. Hence, inferences about differences in hospitalization rates between immigrants and non-immigrants are based on small sample sizes.

An overview of the data on eligibility, coverage, and utilization is shown in Table 2. All means are calculated using sample weights. The first row of Table 2 indicates that 35% of immigrant

17 Some of these physician services would have been rendered in hospitals.

18 An earlier version of this paper broke out children with at least one parent who immigrated less than 10 years ago. In principal, a comparison of these "new" immigrants with all immigrants is of interest because of evidence that new immigrants are less skilled than previous cohorts (Borjas, 1990) and because new arrivals may be less familiar with Medicaid and may face higher transactions costs of enrolling in the program. However, even in a sample as large as the NHIS, there are relatively few children of new immigrants, making it difficult to judge the effects of assimilation. Leclere, Jensen and Biddlecom (1994) find that among adults, recent immigrants are less likely than either the native-born or immigrants of longer duration to receive timely health care.
children are Medicaid eligible, compared to 21% of the children of the native born. This evidence is consistent with previous work which shows that immigrants are more likely than natives to be eligible for social programs. The second row of Table 2 suggests that although a slightly higher fraction of immigrant children are currently covered by Medicaid (18% compared to 14% of children of the native born), average takeup rates conditional on eligibility are actually lower among immigrants--approximately 50% of the Medicaid-eligible immigrant children are covered compared to 66% of eligible children of the native born. Immigrant children are also less likely to be covered by private health insurance, with the result that 25% of the immigrant children are without health insurance coverage compared to 12% of other children.

This large difference in the probability of having health insurance coverage is associated with relatively small differences in the utilization of care, however. The second panel of Table 2 indicates that 19% of immigrant children went without a visit in the 12 months prior to the survey, whether or not they were Medicaid eligible. The comparable figures for children of the native born are 15% for Medicaid eligibles and 16% for non-eligibles, indicating that the differences between natives and immigrants are much greater than the differences between the insured and uninsured. Conditional on having had at least one visit, Medicaid eligible children had slightly more visits. But the difference of .4 or .6 more visits is much smaller than the raw differences between children of the native born and children of immigrants, which are on the order of 1.1 to 1.3 visits. The largest difference between those who are Medicaid eligible and those who are not is in terms of hospitalizations -- native children on Medicaid are almost twice as likely to be hospitalized as those who are not covered.

The last part of Table 2 shows differences in utilization by insurance status and income. These
figures lend support to the view that the private insurance policies held by many low-income households may be less desirable than Medicaid. For example, among natives, 13% of Medicaid households with incomes less than $20,000 (the vast majority of Medicaid households), went without a doctor's visit in the past year. The comparable figure for privately insured households is 19%. It is only in privately insured households with incomes over $40,000 per year that the incidence of going without doctor's visits falls below the Medicaid rate. A similar pattern is evident in immigrant households. Within income brackets, children on Medicaid tend to receive more doctor visits conditional on any visits than the privately insured. And among the privately insured, number of doctor visits increases with income, which may be (at least in part) a reflection of the generosity of the insurance coverage.

What remains to be seen is how much of these raw differences can be explained by the characteristics of immigrant children and their families. Some additional characteristics of children of immigrants and children of the native born and their families are shown in Appendix Table 3. As others have noted, immigrant parents are less skilled on average than other parents. Immigrant families are also poorer, have more children, are more likely to have other adults present in addition to the parents, are less likely to be female headed, and are more likely to live in central cities than other families. These differences will be controlled for in the models estimated below. Thus, these models focus on the differences between immigrants and similar natives, rather than on the differences between immigrants and all natives.
IV. Results

a) Effects of Eligibility on Insurance Coverage

This section investigates the relationship between Medicaid eligibility and type of insurance coverage among children of immigrants and children of the native born. Ordinary Least Squares models of the probability of Medicaid coverage are shown in the first 3 columns of Table 3. Table 1 indicated that immigrants were more likely to be eligible for Medicaid, but had lower takeup rates conditional on eligibility. Controlling for observable characteristics does not change this finding. The first row of Table 3 indicates that becoming eligible for Medicaid increases the probability of coverage among children of the native born by 21 percentage points. The effect of eligibility is somewhat smaller among immigrants, as indicated by the negative interaction between eligibility and an indicator equal to one if the parent is an immigrant. The coefficient on the "parent immigrant" indicator is also significantly negative indicating that children of immigrant parents are less likely to be enrolled in Medicaid conditional on observable characteristics. An F-test soundly rejected the null hypothesis that the combined effect of the parent immigrant indicator and the interaction was zero -- hence, we conclude that eligible immigrants are significantly less likely than similar eligible natives to take up Medicaid coverage. The point estimates suggest that becoming eligible increases the probability of coverage by 18 percentage points among children of immigrants rather than 21 percentage points.  

\[ \text{19} \]

---

\[ \text{19} \] I have also estimated models that exclude parent's education, income, and measures of family structure. These models ask whether take up is similar among immigrants and all natives, rather than focusing on similar natives. The pattern found is qualitatively similar to that reported in Table 3, although the estimated effects of eligibility are larger for both natives and immigrants. For example, eligibility is estimated to increase the probability of Medicaid coverage by 32 percentage points among natives, but by only 22 percentage points among children of immigrants.
The OLS estimates for private insurance coverage and the probability of non-insurance suggest that among natives, most of the increase in Medicaid coverage that accompanies eligibility increases comes at the expense of private health insurance coverage, while among immigrants, some families are dropping or losing private health insurance and becoming uninsured.

There is some evidence in Table 3 that the transactions costs of applying for Medicaid matter, since children in larger families are more likely to be covered than other children (transactions costs imply that there are economies of scale involved in applying for Medicaid). Also, children in central cities where it may be easier to apply are more likely to be covered. Finally, there appears to be a strong seasonal effect -- Medicaid coverage falls in winter and spring relative to summer and fall. This pattern suggests that many parents sign children up for Medicaid in summer and fall in order to get routine care such as immunizations that schools mandate. Then, 6 months later when children must be recertified (in most states), the parents do not renew the child's coverage.

The remaining rows of Table 3 show that for the most part, coverage varies with child and family characteristics as one might expect. For example, children of richer parents are less likely to be covered, while children of less educated parents are more likely to be covered. One noteworthy finding is that the probability of coverage is much higher in families without a male head. This differential may reflect the fact that families on AFDC are already familiar with the welfare system and in most cases are already covered by Medicaid. Finally, although they are not shown, the age dummies included in the regression indicate that younger children are more likely to have coverage, other things being equal. This result may reflect a higher perceived benefit of regular medical care for younger children, or more illnesses requiring care.
As discussed above, it is possible that OLS estimates of the effects of becoming eligible under the Medicaid expansions reflect omitted variables that are correlated both with eligibility and coverage. Suppose for example that some children are both more likely to be eligible, and more likely to have been covered by Medicaid in the absence of the Medicaid expansions, perhaps because they receive AFDC benefits, or because their parents are refugees. In this case, the estimated effect of making someone eligible for Medicaid under the expansions would be biased upwards. Similarly, it is easy to see that OLS estimates of the effect of eligibility on private health insurance coverage are likely to be biased downwards while those on being uninsured are likely to be biased upwards—the same children who are most likely to be made eligible for Medicaid are least likely to have private health insurance coverage and most likely to be uninsured.

The remaining three columns of Table 3 show TSLS estimates of the effects of eligibility on insurance coverage. The estimated effects of eligibility on Medicaid coverage are remarkably robust. Once again, it appears that eligibility raises the probability of Medicaid coverage more among natives than among immigrants (18 percentage points compared to 14 percentage points), and the point estimates are similar to those obtained via OLS. However, instrumenting has a large effect on the estimated effects of eligibility on private health insurance and the probability of being uninsured. While the OLS estimates suggested substantial crowdout of private insurance, the TSLS estimates indicate that most of the gain in Medicaid coverage is in fact coming from the uninsured population.

Are these TSLS estimates reasonable? Note first that although the standard errors are large, the changes in the point estimates are also large. Thus, it is not the case that the effect of eligibility on private insurance becomes statistically insignificant in the TSLS specification solely because of the
increase in the size of the standard errors. Still, it is possible that trends in the private health insurance
market (e.g. concerns about increasing numbers of uninsured among the "working poor") drove some
of the expansions of Medicaid eligibility, which would call these TSLS estimates of the size of
crowdout into question.

One crude specification check involves excluding variables such as parent's education and
income from the TSLS models. If these characteristics are uncorrelated with the fraction eligible in the
state, then the instrumental variables strategy remains valid, and one should obtain the same TSLS
estimates of the effects of Medicaid eligibility whether or not these variables are included. In fact, the
results for Medicaid coverage are qualitatively similar (e.g. larger effects on Medicaid coverage among
natives than among immigrants), but all of the estimated effects of Medicaid eligibility are larger in
absolute value, and the effect of Medicaid eligibility on private health insurance coverage is wrong
signed. Thus, there is some evidence that individual characteristics that affect insurance coverage are
correlated with the fraction eligible instrument. If these characteristics are not adequately controlled
for in the specifications shown in Table 3, then the instrument may be invalid.

In any case, the estimated effect of eligibility on Medicaid may seem low compared to takeup
rates of approximately two-thirds for programs such as Aid to Families with Dependent Children or
Food Stamps. One reason for low takeup rates may be that many of the newly eligible were already
covered by private health insurance. A second consideration is that many of the newly eligible were
unfamiliar with welfare programs in general and unaware that it was now possible for them to qualify
for Medicaid without being on welfare. Third, given transactions costs, many eligibles may not enroll
until they have an urgent need for health care, leading them to cycle on and off the rolls. Short, Cantor,
and Monheit (1988) found that only 43% of Medicaid patients stayed on the program for a continuous 32 month period and that over half of those leaving the program remained uninsured. Cycling will cause the fraction covered to be smaller than the fraction eligible in a cross section.

It is important to keep in mind that these effects are identified using recent changes in Medicaid eligibility, so they should be interpreted as the effect that similar changes or reductions in Medicaid eligibility would have. Evidently, barring all immigrants from receiving Medicaid would have some effect on coverage rates, since some immigrants are in fact covered as shown in Table 2.

b) Effects on Utilization

The discussion of Figures 1 and 2 highlighted the fact that even if children do not take up Medicaid coverage, becoming eligible for Medicaid is likely to make their families better off, and may therefore have some effect on the consumption of Medical care. Alternatively, if we think about the problem from a dynamic point of view, it is clear that eligibility may be more tightly linked to utilization in the past year than Medicaid coverage if children cycle in and out of coverage as needed. This section investigates the effects of eligibility on utilization of care.

The first column of Table 4 shows linear probability models of the effects of eligibility on the probability that a child went without a doctor's visit in the past 12 months. As discussed above, this is the cleanest measure of utilization of health care available in the NHIS since children who do not see a doctor at all are likely to have a true access problem, and to go without necessary preventive care. Becoming eligible for Medicaid is associated with an increase in the utilization of care. The insignificant interaction of immigrant status and eligibility suggests that becoming eligible has the same
effect on all children. However, immigrant parents are about 3 percentage points less likely to have taken their child for a visit in the last year and the increases in eligibility do not seem to have affected this gap.

The second column suggests that while children of immigrants have fewer doctor visits than children of the native born, becoming eligible for Medicaid has little effect on the number of doctor visits among either group, given that they had at least one visit.

Finally, the third column indicates that while children of immigrants are slightly less likely to be hospitalized than other children, becoming eligible for Medicaid increases hospitalizations only among children of the native born. This result is difficult to interpret because hospitalizations are likely to reflect supply as well as demand factors. It is possible for example, that immigrants tend to live near hospitals that supply indigent care, whereas children of the native born tend to live near hospitals that primarily treat the insured. In this case, increases in Medicaid eligibility among previously uninsured children would increase access to hospital care among the native born but not among immigrants. It is also possible that some changes in hospitalization patterns associated with changes in insurance coverage reflect increases in unnecessary hospitalizations.

The remaining columns of Table 4 highlight the fact that many observable characteristics have different effects on utilization than they have on coverage. For example, black children are more likely to have Medicaid coverage, but they are less likely to have received any visits in the past year. Similarly, Table 3 showed that children in large families were more likely to be covered while Table 5 indicates that children in smaller families are more likely to have had a doctor's visit: the latter effect may reflect parental diligence with respect to scheduling the first child's checkups that is relaxed for
later children, or the classic Becker (1981) child quality/quantity tradeoff. And although coverage rates were highest for children with less educated and poorer parents, the probability of receiving any doctor's visits was also lowest for these children. These latter results are consistent with previous evidence that doctor's visits are a normal good, and one which more educated parents tend to value more (c.f. Currie and Thomas, 1995).

As discussed above, these OLS estimates of the effects of eligibility are likely to be biased towards zero if eligible children are those who are most likely to go without medical care for unobservable reasons. TSLS estimates of the effect of eligibility on utilization appear in the last three rows of Table 4. Column 4 suggests that OLS estimates of the effects of Medicaid eligibility on the probability of "no visits" are indeed biased towards zero. Moreover, the bias appears to be greater for immigrants than for natives since the probability of going without a visit declines by 8 percentage points among eligible natives, but by 11 percentage points among eligible immigrants and this difference is statistically significant. Recall that eligible immigrants were less likely to take up Medicaid coverage than eligible natives. Yet they are more likely to receive at least one doctor's visit. The juxtaposition of these results supports the view that immigrants face greater transactions costs than natives, and hence spend more time without formal Medicaid coverage. On the other hand, neither the OLS or TSLS results show any effect of eligibility on the number of doctor visits conditional on the child having had at least one visit.

Finally, OLS estimates of the effects of eligibility on hospitalizations also appear to be biased

---

20 Alternatively, larger families have lower per capita incomes and may therefore purchase fewer normal goods such as health care.
towards zero, though instrumenting does not change the qualitative finding that eligibility increases hospitalizations among natives but not among children of immigrants. The effect for children of the native born is large (implying a 100% increase in hospitalizations) but consistent with what was shown in the means in Table 2.

A specification check similar to that described above was conducted for the models shown in Table 4. That is, the TSLS models were re-estimated excluding variables such as parent's education, income, and family structure. The resulting estimates were extremely similar to those reported in Table 4. Thus, there is little evidence that these measurable individual characteristics are correlated with both utilization of care and the fraction eligible instrument in a way that would invalidate the instrument. The conclusion that can be drawn is that the TSLS results regarding utilization are more robust than those regarding insurance coverage. In particular, it is difficult to draw any conclusions regarding the extent to which public insurance has crowded out private insurance using these data.

V: Discussion and Conclusions

This paper demonstrates that children of immigrants are more likely than other children to be eligible for Medicaid. Despite higher eligibility levels, the fraction of children covered by Medicaid is only slightly higher among immigrant children, which indicates that immigrants have lower average takeup rates. Moreover, recent eligibility expansions increased coverage more among natives than among immigrants, and this is true whether or not characteristics such as parental education, income, and family structure are controlled for.

The eligibility expansions had quite different effects on the utilization of care, suggesting that a
narrow focus on coverage can lead to quite misleading assessments of the costs and benefits of extending eligibility. Becoming eligible for Medicaid reduced the probability that a child went without a doctor’s visit in the past year dramatically for both immigrants and non-immigrants. On the other hand, becoming eligible was not associated with an increase in the number of doctor visits given at least one visit among either group of children, and was associated with greater increases in hospitalization rates among children of the native born but not among children of immigrants.

Thus, among immigrants the main effect of becoming eligible for Medicaid was to reduce the number of children going without any doctor visits. As discussed above, in 1997 there were 12 million children with at least one immigrant parent. If we follow Table 2 and assume that 35% of these children are eligible for Medicaid, then if Medicaid caused 11% of these children to receive an additional doctor visit at a cost of $50 per visit, the total bill would be approximately $2.3 million dollars per year.

Hence, the *marginal cost* of extending Medicaid eligibility to children of immigrants appears to have been small. These results do not imply that the total cost of providing Medicaid to immigrant children is insignificant—as discussed above, the U.S. has been spending on the order of $5.5 billion per year on Medicaid payments for children of immigrants. The key point is that reducing Medicaid eligibility for these children will not necessarily save money as long as children remain eligible for costly emergency care. In fact, costs could increase if lack of preventive care eventually increases the number of emergency cases.

Notes: The 75%, 22%, and 50% figures are based on the maximum AFDC benefit levels for these states. Children born after Sept. 30, 1983 were eligible for Medicaid if their families were income-eligible for AFDC. Older children were eligible only if their parents actually qualified for AFDC (i.e. met all other requirements as well as income-eligibility). By 1989, states were required to cover children through age 6 if their families were income eligible for AFDC.

Figure 1: The Role of Transactions Costs
Appendix Table 1: The Medicaid Expansions

**Deficit Reconciliation Act, 1984:** Effective October 1, 1984. Required states to extend Medicaid coverage to children born after September 30, 1983, if those children lived in families that were income-eligible for AFDC.

**Omnibus Budget Reconciliation Act, 1986:** Effective April 1, 1987. Permitted states to extend Medicaid coverage to children in families with incomes below the federal poverty level. Beginning in fiscal year 1988, states could increase the age cutoff by one year each year, until all children under age five were covered.

**Omnibus Budget Reconciliation Act, 1987:** Effective July 1, 1988. Permitted states to cover children under age 2, 3, 4, or 5, who were born after September 30, 1983. Effective October 1, 1988, states could expand coverage to children under age 8 born after September 30, 1983. Allows states to extend Medicaid eligibility to infants up to one year of age in families with incomes up to 185% of the federal poverty level. States were required to cover children through age 5 in fiscal year 1989, and through age 6 in fiscal year 1990, if the families met AFDC income standards.

**Medicare Catastrophic Coverage Act, 1988:** Effective July 1, 1989, states were required to cover infants up to age one in families with incomes less than 75% of the federal poverty level. Effective July 1, 1990, the income threshold was raised to 100% of poverty.

**Family Support Act, 1988:** Effective April 1, 1990. States were required to continue Medicaid coverage for 12 months among families who had received AFDC in three of the previous six months, but who had become ineligible because of earnings.

**Omnibus Budget Reconciliation Act, 1989:** Effective April 1, 1990. Required states to extend Medicaid eligibility to children up to age 6 with family incomes up to 133% of the federal poverty line.

**Omnibus Budget Reconciliation Act, 1990:** Effective July 1, 1991. States were required to cover all children under age 19 who were born after September 30, 1983 and whose family incomes were below 100% of the Federal poverty level.

This appendix describes the procedure for imputing the Medicaid eligibility of individuals in the CPS and NHIS. The source for information on state Medicaid options is National Governors Association (various years) and Congressional Research Service (1988, 1993).

a) Eligibility for AFDC

In order to qualify for AFDC, the child's family must satisfy three tests: 1) gross income must not exceed 1.85 times the state need's standard, 2) the gross income less certain "disregards" must be below the state needs standard, and 3) the gross income less the disregards, less a portion of their earnings, must be below the state's payment standard.

The disregards can be computed as follows. Beginning in October 1981, the allowance for work and child care expenses was $75 per month for work expenses and a maximum of $160 per child for child care costs. These allowances were not changed until the Family Support Act of 1988, which raised the allowances to $90 for work expenses and $175 per child for child care expenses, effective October 1, 1989. In addition, a portion of earned income was disregarded. In 1984, women were allowed to keep $30 plus 1/3 of earned income for four months. From 1985 onwards, individuals who would have become ineligible for AFDC (and hence for Medicaid) after the 4 months were allowed to remain eligible for Medicaid for an additional 9 to 15 months depending on the state. We modeled this by assuming that for Medicaid eligibility purposes, women were allowed to keep the $30 and 1/3 of earned income for a year. The aim was to consistently model the maximum amount that a person could have received while remaining eligible for Medicaid coverage under AFDC.

One difficulty in implementing these rules in the NHIS is that the disregards apply only to earned income and one cannot distinguish between earned income and other income. It is therefore assumed that all household income is earned. This assumption yielded AFDC eligibility findings in the NHIS that were similar to those from the CPS, where there is data on individual earnings by source.

The second set of rules that must be evaluated to see if a child is eligible for AFDC are rules relating to family structure. Eligibility under the traditional program requires that the child reside in a female-headed household. However, children in two-parent households may still have been eligible under the AFDC-UP program. Eligibility for AFDC-UP conditions on both current employment status and work history. Data on AFDC-UP regulations are from Hoynes (1993). In addition, some states covered families with Medicaid if they had an unemployed head, even if there was no AFDC coverage; these states are identified in National Governor's Association (various years).

Lacking longitudinal data on work histories, it is assumed in the CPS that families are
eligible if the state has a program, and the spouse had worked less than 40 weeks in the previous year. In the NHIS it is only possible to determine whether or not the spouse is currently unemployed. Hence, the estimate of the AFDC-UP caseload is biased upwards because it is not possible to determine whether those who are unemployed have been attached to the labor force long enough to qualify for AFDC-UP. Still, our estimates of the size of the AFDC-UP caseload appear to be reasonable as about 1 in 20 AFDC eligibles are estimated to qualify through that program, matching the ratio reported in administrative data.

b) Eligibility under state Medically Needy programs.

In some states, children in families with incomes too high for AFDC could qualify for Medicaid under state Medically Needy programs. Income thresholds for these programs could be set no higher than 133% of the state's needs standard for AFDC. Families could "spend down" to these thresholds by subtracting their medical expenditures from their gross incomes (less disregards) -- if they did so, then Medicaid would pay the remainder of their medical expenses. In order to qualify, however, families must have high medical expenditures for several consecutive months (the "spend down period"). There is no way to determine which families have had such high medical spending in the CPS, and I do not do so in the NHIS since eligibility would then be a direct function of utilization and health. As an approximation, eligibility thresholds are set to the Medically Needy levels in states with this program. Data on Medically Needy coverage and thresholds is from National Governors Association (various years).

c) Eligibility for Ribicoff children.

Ribicoff children are those who would qualify for AFDC given income criteria alone, but who do not qualify for reasons of family structure. States may or may not choose to cover children under this optional program. In states that do cover them, the family structure requirements are ignored and screening is done only on income. Some states cover selected groups of children (such as only those in two parent families, or only those in institutions). However, it was not possible to obtain precise information on the groups of children covered. Hence, states are counted as a "Ribicoff state" only if it covers all categories of children, as reported by the National Governors Association. Currie and Gruber also tried calling all of the states to obtain information about their Ribicoff children program; the resulting information appeared unreliable, since almost every state said that they had a program whereas secondary sources report that coverage is much more selective. Using the state self-reported coverage yielded similar results to those reported in the paper.

d) Eligibility under the Medicaid Expansions.

See Appendix Table 1 for a summary of the relevant legislation. If family income and the child's age were less than the cutoffs, it was assumed that the child was eligible. One important question is whether states apply AFDC disregards when computing a family's eligibility for the expansions. Discussions with several state and federal Medicaid administrators suggested that
such disregards were generally applied, so they were used in our eligibility calculations. Calculating eligibility without the disregards yielded a significantly smaller effect of the expansions, but the regression results were quite similar.
