Abstract

We study how political preferences shaped California’s High-Speed Rail (CHSR), a large transportation project approved by referendum in 2008. Across census tracts, support for the project responded significantly to the projected economic gains at the time of voting, as measured by a quantitative model of high-speed rail matched to CHSR plans. We estimate that 0.1%-0.2% projected economic gains swayed 1% of votes at the median tract. Given this elasticity, a revealed-preference approach comparing the CHSR with counterfactual designs identifies strong policymakers’ preferences for political support. A politically-blind planner would have placed the stations nearer to California’s dense metro areas, doubling the projected economic gains.

*We thank Andrii Parkhomenko, Jonathan Dingel, and Giacomo Ponzetto for their conference discussions, and seminar participants at ASSA Meetings, Berkeley, Chicago, CREI, Chicago-Princeton Spatial Economics Conference, Harvard-MIT, Michigan, NBER Transportation, Penn State, St. Louis Fed, SED, Tinbergen, Toronto, UC Irvine, UCLA ITS, University of Washington, UTDT, West Coast Spatial Workshop, and Wisconsin for helpful feedback. We thank the NBER and the US DOT for financial support. Cecile Gaubert acknowledges support from NSF CAREER grant #1941917. Edouard Schaal acknowledges financial support from the Spanish Ministry of Economy and Competitiveness, through the Severo Ochoa Programme for Centres of Excellence in R&D (SEV-2015-0563) and the European Research Council Starting Grant 804095. This study was made possible with funding received by the University of California Institute of Transportation Studies from the State of California for the California Resilient and Innovative Mobility Initiative (RIMI). This paper is disseminated under the sponsorship of the State of California in the interest of information exchange and does not necessarily reflect the official views or policies of the State of California.
1 Introduction

The efficiency of transportation systems constitutes a central question in spatial economics. Using quantitative spatial frameworks, recent research has studied the optimality of transport networks, finding that inefficiencies are pervasive and that observed transport systems could have been designed in alternative welfare-improving ways. Recent studies include Fajgelbaum and Schaal (2020) and Allen and Arkolakis (2022) for highways, Brancaccio et al. (2024) for ports, Kreindler et al. (2023) and Almagro et al. (2024) for bus systems, and Frechette et al. (2019), Buchholz (2022), and Brancaccio et al. (2023) for taxis or bulk shipping.

Why are transport networks inefficient? In this paper, we study the role of policymakers’ and households’ preferences in shaping the projects that are implemented. In the process of designing transport networks, policymakers may take into account the popular approval elicited by these projects, as well as distributional impacts among constituencies. Investments driven by these motives—for example, targeting areas to maximize political support—will generally differ from investments driven by aggregate welfare considerations alone. Quantifying these differences requires a methodology to estimate the weight that these motivations play in the planner’s preferences, as well as gauging whether, and by how much, public support responds to the economic impacts of transport investment projects.

We make progress on these questions in the context of California’s High-Speed Rail (CHSR), one of the most expensive transport projects attempted in U.S. history. On occasion of the 2008 general election, Proposition 1A asked Californians whether they approved of initiating funding for the CHSR (passing with 52.6% in favor). The features of the project that were known when voting—manifested through business plans, environmental reports, and the ballot’s text—resulted from years-long planning by authorities who anticipated putting the CHSR up to a public vote.

We estimate Californian politicians’ and voters’ preferences, and study their role in shaping the proposed CHSR. To that end, we use a novel framework of optimal high-speed rail network design combined with voting data and CHSR planning data. We first develop and estimate a spatial model that incorporates specificities of high-speed rail passenger travel. Then we estimate, using census-tract data, the relationship between favorable votes in the 2008 referendum and the expected local economic impacts of the CHSR as predicted by our spatial model. To address endogeneity concerns, we build instruments based on random station placements along alternative CHSR designs entertained early in the planning process. Finally, we embed both the spatial model and the estimated voters’ preferences into the problem of a politically-minded planner who decides where to locate stations. We estimate bounds on the policymakers’ preference parameters by comparing the actual CHSR design with alternative designs that were not selected by the policymakers.

---

1Since it was approved by referendum in 2008, the CHSR has been mired in a myriad of financial, legal, and implementation troubles; doubts linger on whether it will ever be operational. Our focus is not on understanding why the project faced so much trouble, but on studying what its initial design reveals about the preferences of voters and policymakers for this infrastructure project; and in turn on determining how these preferences shaped its design. We do incorporate the possibility of failure in the expectations of voters and policymakers, as we explain in detail below.
finally solve for the optimal placement of stations under alternative policymakers’ preferences.

We summarize three main takeaways of our analysis. First, we find voters responded significantly to the model-implied projected economic impact of the CHSR in their tract of residence. This result gives credibility to our estimated model as a predictor of the spatial distribution of economic impacts of the CHSR. It also shows that economic voting may be a significant driver of policy preferences over transport infrastructure. Second, the CHSR design implies strong planner preferences for votes: deviations that would have increased aggregate welfare, but reduced votes, were not implemented. Third, in the absence of these preferences for votes, the optimal CHSR design would have concentrated stations closer to urban areas, where it was harder to sway votes, and this would have doubled the projected gross economic benefits of the CHSR. We thus conclude that attaining popular approval was an important driver of the CHSR design.

We now describe each step of our analysis. First, we develop and estimate a quantitative spatial model of high-speed passenger travel. The goal of the model is to obtain the distribution across census tracts of the relative real-income impacts of the CHSR, to then use voting data from the 2008 referendum to estimate the responsiveness of votes to these relative impacts. Compared to canonical urban frameworks centered on commuting, such as Ahlfeldt et al. (2015) and Monte et al. (2018), our model includes three distinct features. First, while facilitating commuting into urban centers is an important role of high-speed rail systems (Zheng and Kahn, 2013), long-distance rail connections also confer benefits to infrequent business or leisure travelers. We incorporate these additional travel purposes, and rely on the California Household Travel Survey to quantify the parameters determining their importance. Second, as CHSR usage would depend on access to competing travel modes, we include a choice over transport modes (between car, air, and public transit) for each origin-destination pair and travel purpose. Third, we incorporate that travel decisions depend both on travel time (as in standard frameworks) and on monetary trip costs, an a priori relevant feature given the low ticket prices announced by CHSR planners.

To estimate the key model parameters, we rely on gravity equations for commuting, leisure, and business travel across California’s census tracts. The resulting estimates reveal how travel time and cost differences by route are valued by Californians, as well as how preferences over different travel modes vary across regions, demographic groups, and travel purpose. Using the estimated model, we then simulate travelers’ choices over destinations and mode of transport in the hypothetical scenario in which the CHSR becomes available, and obtain as a result the spatial distribution of the potential real income effects of the CHSR across 7866 census tracts.

---

2We model long-distance business and leisure travel decisions as including an intensive margin, the number of trips, which we observe in the data. We model business travel as an input in production, with firms (rather than travelers) deciding the destination of business trips as a function of characteristics that make certain destinations more profitable for business connections. Through this channel, the high-speed rail network may affect TFP by better matching business travelers to business hubs. Bernard et al. (2019) and Dong et al. (2020) provide evidence that the high-speed rail in Japan and China, respectively, raised business or research productivity by facilitating face-to-face interactions.

3The prices projected in the 2022 update to the CHSR business plan are considerably higher than the 2008 forecasts. We account for both of these forecasts by considering alternative scenarios when quantifying our model.

4Our setting is sparse, with about 15 million workers for about 64 million origin-destination pairs of census tracts;
Our model predicts that larger urban centers such as San Francisco or Los Angeles, and areas closer to the location of the planned CHSR railway stations, would on average benefit relatively more from the implementation of the CHSR; in contrast, more sparsely populated areas like Central-Valley have lower potential gains. These model-based predictions are qualitatively consistent with existing empirical assessments of passenger transport systems. Moreover, as shown in the next step, the voting patterns in the 2008 referendum responded to these model-implied real income gains from the CHSR, providing validation of the model predictions.

We compute these model-implied real-income gains of the CHSR using official CHSR business plans as available in two different years: 2008 (when the vote took place) and 2022 (the most recent year with a business plan). The 2008 information turned out to be unrealistic: the construction of the CHSR progressed at a much slower pace and costs were higher than forecasted. In contrast, the 2022 CHSR business plan acknowledges risk, costs, and timeline increases. Whether we use the 2008 or the 2022 scenarios affects the mean and variance of the distribution of CHSR’s economic impacts across tracts, but not the ranking of winners and losers: the cross-tract correlation of the economic impacts when using 2008 and 2022 forecasts is 99%. We use this distribution to estimate if there was a response of votes to expected income in the next step.

In the second step, we estimate the elasticity of favorable votes in the 2008 referendum to the model-implied expected economic gains from the CHSR. Identifying this response is key for our goal of determining whether planning authorities took into account public support when deciding the design of the CHSR. By following a structural approach to measure the private economic benefits of a policy, we depart from the prior literature that tries to determine the role of those benefits in voters’ choices; these previous studies project votes on reduced-form variables that plausibly capture individual exposure to a policy. Our reliance on a structural model is essential to recover a structural elasticity and to characterize counterfactual optimal networks.

Our structural approach is not exempt from identification challenges, crucially the possibility that the model-implied economic benefits of the CHSR are correlated with other variables, such as preferences over public goods or political ideology, that also impacted voters’ support for the CHSR. To deal with these identification challenges, we follow different approaches. First, we moreover, the long distance travel information that we use comes from travel surveys collected on limited samples. Consequently, to avoid that our estimates of model parameters are affected by an incidental parameters problem, we follow the suggestion in Dingel and Tintelnot (2020) and project all travel costs and destination-specific effects on vectors of observed characteristics.

Recent studies of the the spatial impacts of public transit systems include Tsivanidis (2019) for rapid buses in Bogota, Severen (2021) and Tyndall (2021) for the light rail in Los Angeles and other US cities, Gupta et al. (2022) for the NYC subway, Zárate (2022) for subway lines in Mexico City, Khanna et al. (2023) for cable-car in Medellin, and Borusyak and Hull (2023) for the Chinese rail. Broadly speaking, these studies find positive impacts of proximity to transit connections on commuting flows, formal employment, wages, or land prices. Koster et al. (2022) finds employment losses for smaller areas connected to the Japanese high-speed rail.

E.g., Van Patten and Méndez (2022), studying a referendum in Costa Rica on whether to sign a FTA with the U.S., project favorable votes on voters’ exposure to U.S. trade. Following Deacon and Shapiro (1975), many studies use ballots to draw inference about demand for private versus collective goods. Kahn and Matsusaka (1997) and Holian et al. (2013) correlate votes in ballot initiatives, including the CHSR Proposition 1A, with proxies for economic exposure such as industry of voters. Alesina and Giuliano (2011) review research that uses survey data to measure preferences for private vs. public value in income taxation.

Voting on subjective considerations is referred to as expressive voting in the political sciences literature (Hillman,
control for a host of tract-level covariates including county fixed effects, demographic characteristics, Democratic party affiliation, and votes in related referenda favoring green energies or transportation initiatives. Second, we instrument for the economic impact of the CHSR using alternative CHSR designs with random placement of stations across feasible routes identified by planners years prior to the vote. Third, we conduct the estimation under different model specifications in terms of economic mechanisms and voters’ expectations on CHSR costs and benefits at the time of voting.

Regardless of the model variant and the identification strategy, we find that voters are responsive to the model-based expected economic impact of the CHSR. Moreover, once we instrument, this elasticity is robust to the set of controls. Depending on whether 2008 or 2022 cost predictions are used, an extra 0.1-0.2 percentage points in local expected economic gains swayed one percentage point of local votes (the standard deviation of votes across tracts was 0.1 percentage points, and that of model-based income gains was 0.1-0.2 percentage points depending on model variant). This responsiveness implies that policymakers who value public support may have shifted the supply of infrastructure towards certain areas based on the marginal impact on public support, at the expense of where it may have been socially more desirable.

In the third and final step, we estimate the preferences of a social planner designing the CHSR, and then compute counterfactual optimal designs under alternative preferences. We model a policymaker choosing the distribution of stations along the main technologically feasible routes linking Northern and Southern California, as identified by transport engineers several years prior to the 2008 vote (US DOT, 2005). We assume that the observed CHSR design maximized an objective function with two components: a weighted sum of the tract-specific real income impacts of the CHSR (with tract-specific Pareto weights as function of demographics), and the total public support in favor of the project.

To estimate the planner’s preferences, we follow a revealed-preference approach in the spirit of Goldberg and Maggi (1999) in international trade and Bourguignon and Spadaro (2012) in public finance. Our approach more specifically relates to Adão et al. (2023)’s analysis of U.S. tariffs. Like them, we use a fully-specified quantitative model to construct perturbations of the planner’s objective function in response to counterfactual policies, and then estimate the planner’s preferences that rationalize the observed policy as maximizing the value of the planner’s objective function.

A challenge in our context is that closed-form solutions for optimal policies, which are typically used in the previous literature, are unavailable. Furthermore, marginal perturbations to stations’ locations have little identifying power. Our approach therefore uses discrete deviations from the observed station placement –for example, by shifting a CHSR station from its designated location to the next-largest urban area without a proposed station. In doing so, we derive revealed-preference moment inequalities following Pakes (2010) and Pakes et al. (2015). These deviations set bounds

---

Burgess et al. (2015) and Alder and Kondo (2020) find empirical evidence that a president’s ethnicity or birthplace explains patterns of road investments in Kenya and China, respectively.
on the planner’s preferences; for instance, deviations that increase aggregate votes but reduce aggregate income define an upper bound on how much the planner likes the former relative to the latter. We use the moment-inequality inference procedure in Andrews and Soares (2010) to compute confidence sets for the planner’s preference parameters.

Our results show strong planner preferences for votes, as well as some preference for areas with a larger share of college graduates. The planner is, thus, far from the utilitarian benchmark. Finally, we compute optimal networks under counterfactual planner preferences. The optimal CHSR design for an apolitical planner differs substantially from the proposed plan, with many stations located closer to the main metropolitan areas. The reason is that these metro areas have low voting elasticities: they would support the construction of the CHSR regardless of their private economic gains from it; in the absence of electoral motives, policymakers would have placed stations closer to these locations. Furthermore, this reallocation would double the model-implied aggregate economic gains of the CHSR. Nearly all of the difference between the observed CHSR design and that selected by a purely utilitarian planner comes from the preferences for votes, while the estimated heterogeneity in the planner’s Pareto weights plays a minor role.

The paper proceeds as follows. Section 2 gives some background on the CHSR design process and implementation. Section 3 lays out our quantitative economic model. Section 4 presents the data, the estimation of the model parameters, and the estimation of voters’ preferences. Section 5 estimates the planner’s preferences and presents model-based counterfactuals. Section 6 concludes. A full description of the model as well as details on data sources and implementation appears in the Online Appendix.

2 Background

In 1996, the California state legislature established the California High Speed Rail Authority (CAHSRA) to explore the creation of a high-speed rail network that would connect the main urban centers in northern California to those in southern California. In August 2008, the California legislature approved that Proposition 1A would appear on the ballot on occasion of the November 2008 general election, asking California voters to approve the issuance of nearly $10 billion in bonds to initiate funding for the CHSR, to be complemented by federal funding and private investors.

The CHSR project described in Proposition 1A had to satisfy several criteria. First, it had to connect San Francisco to Los Angeles and Anaheim, and include stations in Sacramento, the San Francisco Bay Area, the Central Valley, the Inland Empire, Orange County, and San Diego. Second, it had to travel at 200 miles per hour or faster, making the trip from San Francisco to Los Angeles Union Station in at most two hours and 40 minutes. Third, the maximum number of stations in the entire network was 24. Fourth, it had to be completed by 2033.

Proposition 1A was approved by 52.6% of votes. Participation was high, equal to 94% of voters who cast a vote for president in the same election. Figure 1 shows the share of positive votes on Proposition 1A in each census tract. Each point is the population centroid of a tract; in denser
areas the entire tract is colored. Bright yellow areas were more supportive, while dark blue areas were less supportive. Broadly speaking, support was stronger in urban centers (Los Angeles, San Diego, San Francisco, San Jose, Fresno, and Sacramento) and declining in distance to the railway line. Counties of the greater San Francisco bay area (e.g., Marin and Sonoma) show clusters of strong support, while in Los Angeles the support is more concentrated in central areas.

Construction began in 2015, suffering many technical, legal, and financing troubles since then; construction has ran behind schedule and costs have bloated. Construction is now focused on the Central Valley segment, a 180 miles-long stretch (out of the CHSR approximately 800 miles) that is expected to be completed by the mid 2030s. The estimated total costs for Phase I of the project have roughly doubled from around $50 billion in 2008 (California High Speed Rail Authority, 2008) to around $100 in 2022 (California High Speed Rail Authority, 2022).

Voters may have expected by 2008 that the description of the CHSR project in Proposition 1A was too optimistic. We incorporate this possibility into our analysis below, by considering voters’ expectations that align either with the projections in the 2008 plan or with updated projections released in 2022.

3 Framework

This section gives an overview of the theoretical framework. We outline our assumptions on voters’ preferences as well as the model of the CHSR’s economic impacts. We defer the discussion of the planner’s problem to Section 6.
3.1 Utility and Voting

Consider a resident $\omega$ of a location $i$. Her utility $u_{\omega}(s)$ depends on whether the CHSR is approved to be built ($s = Y$ for Yes) or not ($s = N$ for No). We assume:

$$u_{\omega}(s) = \mathbb{E} \left[ \ln W(i, s) \mid I_i \right] + \ln a(i, s) + \varepsilon_{\omega}^u(s). \tag{1}$$

The first component, $\mathbb{E} \left[ \ln W(i, s) \mid I_i \right]$, is the expected real income of residents of location $i$ in state $s$. The expectation is taken over the distribution of future shocks to fundamental economic characteristics in all locations, conditional on the current information set $I_i$ of residents of location $i$. We describe the term $\ln W(i, s)$ next, in Section 3.2. The second component, $\ln a(i, s)$, captures other determinants of preferences for the CHSR that are common across all residents of location $i$; e.g., political affiliation or environmental preferences. Finally, $\varepsilon_{\omega}^u(s)$ captures individual-specific preferences, stemming from economic and non-economic considerations.

Individuals vote for the policy option $s$ that delivers the highest utility. Aggregating over individuals, our setup corresponds to a probabilistic voting model (Deacon and Shapiro, 1975), with the fraction of positive votes for the CHSR in location $i$ defined as:

$$v(i) = \Pr [u_{\omega}(Y) > u_{\omega}(N)]. \tag{2}$$

We assume the idiosyncratic shocks $\varepsilon_{\omega}^u(s)$ are iid across residents and type-I extreme-value distributed with shape parameter $\theta_V$:

$$\Pr (\varepsilon_{\omega}^u(s) < x) = e^{-e^{-\theta_V x}}. \tag{3}$$

As a result, the fraction of voters in location $i$ that support the CHSR takes the standard logit form:

$$v(i) = \frac{e^{\theta_V (\mathbb{E}[\ln \hat{W}(i) \mid I_i] + \ln \hat{a}(i))}}{1 + e^{\theta_V (\mathbb{E}[\ln \hat{W}(i) \mid I_i] + \ln \hat{a}(i))}}. \tag{4}$$

In this expression,

$$\hat{W}(i) \equiv \frac{W(i, Y)}{W(i, N)} \tag{5}$$

measures real income differences in location $i$ depending on whether the CHSR vote is approved, while $\hat{a}(i) \equiv a(i, Y) / a(i, N)$ measures other determinants of preferences for the project.

3.2 Quantitative Model of High-Speed Rail

We measure the economic impacts of the CHSR using as basis a commuting model à la Ahlfeldt et al. (2015) augmented to allow for: long-distance leisure and business trips; a mode-of-travel decision with location-specific preferences over travel modes; a monetary cost of travel; and uncertainty over project completion when calculating welfare. We provide here an overview of the model, and include a complete description in Appendix A. As in the previous section, $\hat{X}$ means the ratio between the value of variable $i$ when the CHSR vote is approved and when it is not.
If the CHSR is approved, households expect to start paying right away a yearly tax \( t \) to fund the capital costs of the full CHSR project. Voters are however uncertain over the project completion: they expect the CHSR to be operational no sooner than \( T \) years after the vote, with a yearly probability of completion equal to \( p \) afterwards. Hence, if approved, the annualized net (log-) real-income impact of the CHSR is:

\[
\ln \hat{W}(i) = (1 - R) \ln (1 - t) + R \ln \hat{V}(i), \tag{6}
\]

where \( R \equiv (1 + r)^{-T} \frac{p}{1 + p} \) is an effective discount rate that incorporates the time discount \( t \) and non-completion risk; and \( \hat{V}(i) \) captures net real income impacts of the CHSR conditional on becoming operational.

To evaluate \( \hat{V}(i) \), we assume residents of a location \( i \) choose a location where to work, and also make infrequent leisure and business long-distance trips.\(^9\) Travelers for any of these purposes (commuting, business, or leisure) perceive different destinations as imperfect substitutes. Travelers also make a choice of transport mode on each origin-destination pair, perceiving different travel modes as imperfect substitutes. Commuters choose between car, public transit, and walking/biking; and long-distance travelers choose between car, public transit, and air.

Residents from different origins may vary in their preferences for each travel mode (e.g., everything else equal, some demographic groups may have a stronger preference for traveling by car than via public transit). Data on mode usage by census tract allows to estimate these tract-specific preferences for modes of transport. However, the lack of data on CHSR usage implies that preferences for it must be assimilated to preferences for one of the available modes. We assume that, if available, the CHSR would be perceived as a perfect substitute for public transit in the case of commuters; and as a perfect substitute for air travel in the case of business and leisure travelers. Of course, someone initially traveling by car may choose to switch travel mode and use the CHSR when available.

To account for the possibility that workers may internalize to different extents the impact that the construction of the CHSR will have on equilibrium prices, we consider two model variants: a simple baseline model with fixed wages and land prices, and a more sophisticated general equilibrium model.

In our baseline model, the economic impacts of the CHSR come exclusively from changes in the time and monetary cost of traveling, and from the tax required to finance the infrastructure. Given the microfoundation in Appendix A, the annual real-income change for residents of tract \( i \) if the CHSR becomes operational, \( \hat{V}(i) \), can be written as follows:

\(^9\)We let the development of the CHSR impact commuting and travel choices, but assume it does not impact residential choices. If residential choice was incorporated in the framework, workers would value not only the impact of the CHSR on their tract of residence (as in the current model) but also the average impact over potential migration destinations. In Section 5, we show there is a significant response of voting decisions to own-tract economic outcomes, consistent with voters believing in 2008 that the economic impact of the CHSR in their location of residence will affect them in the future. An extension where workers face a constant per-period probability of migration would preserve a log-linear relationship between \( \hat{W}(i) \) and \( \hat{V}(i) \) as in 6, although with different structural parameters in that relationship.
\[ \hat{V}(i) = \hat{\Omega}_C(i) \hat{\Omega}_L(i). \] (7)

The component \( \hat{\Omega}_C(i) \) equals the change in labor income net of commuting cost. More specifically, it captures commuters’ expected time savings and changes in travel costs, and it can be written as:

\[ \hat{\Omega}_C(i) \equiv \left( \sum_{j \in J} \sum_{m \in M_C} \lambda_C(i, j, m) \left( \frac{\hat{I}(i, j, m)}{\hat{\tau}(i, j, m)^\rho} \right) \right)^{\frac{1}{\epsilon_C}}. \] (8)

In this expression, \( \hat{I}(i, j, m) \) is the change in disposable income for a commuter from residence tract \( i \) to workplace tract \( j \) using transport mode \( m \). A commuter’s disposable income is impacted by the CHSR through two channels: the train ticket price and the tax levied to finance the CHSR’s capital costs.\(^{10}\) The term \( \hat{\tau}(i, j, m) \) is the change in travel time from \( i \) to \( j \) through mode \( m \), converted into a dollar-equivalent value by the elasticity \( \rho \). The elasticity \( \theta_C \) captures the extent to which residents substitute across commuting destinations or travel modes when their relative appeals change. Finally, for each \((i, j, m)\), the corresponding changes in time and monetary costs are weighted by the share \( \lambda_C(i, j, m) \), the fraction of tract-\( i \) residents that commute to \( j \) using mode \( m \) in the equilibrium without the CHSR. These shares capture heterogeneous tract-specific preferences over transport modes and commuting destinations.

The second component of (7), \( \hat{\Omega}_L(i) \), captures the economic impact of the CHSR on leisure travel. This term is also a weighted average of time and cost changes:

\[ \hat{\Omega}_L(i) \equiv \left( \sum_{j \in J} \sum_{m \in M_L} \lambda_L(i, j, m) \left( \hat{p}_L(i, j, m) \hat{\tau}(i, j, m)^\rho \right) \right)^{\frac{1}{\epsilon_L}}. \] (9)

The term \( \lambda_L(i, j, m) \) is the fraction of leisure travelers from \( i \) to \( j \) using mode \( m \) absent the CHSR, \( \hat{p}_L(i, j, m) \) is the change in the ticket cost of travel, \( \hat{\tau}(i, j, m)^\rho \) is the monetary-equivalent change in the time cost of travel, and \( \theta_L \) captures how substitutable destinations and transport modes when traveling for leisure. Compared to equation 8, the expression in equation 9 accounts for the fact that not all workers travel for leisure through the share of leisure travel in total expenditure, \( \mu_L \).\(^{11}\)

Equations 7 to 9 completely determine the real-income effects of the CHSR in our baseline model. In short, these reduced-form equations capture weighted averages of time- and cost- changes from the CHSR, with tract-specific weights that capture the likelihood that the CHSR will be adopted given the observed travel patterns of each tract, and with elasticities that capture the value of time and the rate at which residents substitute travel modes and destinations.

\(^{10}\)Specifically, with direct effects only, the change in disposable income, defined in (A.34), is \( \hat{I}(i, j, m) = (1 + \chi^{pre}(i, j, m)) (1 - t) - \chi^{pre}(i, j, m) \hat{p}_C(i, j, m) \), where \( \chi^{pre}(i, j, m) \) is the share of commuting costs in disposable income for someone traveling from \( i \) to \( j \) through mode \( m \) before the CHSR is operational, \( \hat{p}_C(i, j_C, m_C) \) is the change in the monetary cost of this commuting route, and \( t \) is the tax levied to finance the CHSR’s capital costs.

\(^{11}\)There are two key differences between (8) and (9). First, the monetary cost of travel enters as a negative additive shifter in disposable income \( \hat{I}(i, j, m) \) in (8), while it enters multiplicatively in (9). Second, the role of the monetary cost of travel is modulated by the share of spending in leisure travel, \( \mu_L \), in (9). These differences reflect the different ways in which commuting and leisure travel enter in preferences. Spending on commuting is non-homothetic: travelers spend a fixed amount of money in commuting, with the remaining income divided between consumption, housing, and leisure trips. The division of income across leisure trips, consumption, and housing is conversely determined according to a homothetic function, with spending shares possibly varying across tracts.
In our general-equilibrium model (the “GE” model), the CHSR further impacts local amenities and productivities, land rents, and wages. For example, local productivities change through two mechanisms. First, through standard spillover effects: as workers change their workplace location in response to the CHSR, worker density may change and, as result, location-specific productivities change. Second, through business trips. Specifically, total factor productivity in tradable goods changes as follows:

$$\hat{\Omega}_B(i) = \hat{A}(i) \left( \sum_{j \in J} \sum_{m \in M_B} \lambda_B(i,j,m) \left( \frac{\hat{A}(j)}{\hat{p}_B(i,j,m) \hat{\tau}(i,j,m)^\mu} \right)^{\frac{1}{\theta_B}} \right)^{\frac{1}{\theta_B}}. \quad (10)$$

The productivity benefits of business trips depend positively on the productivity at the destination \(A(j)\), and negatively on the time and monetary cost of business trips. The term \(\lambda_B(i,j,m)\) is the fraction of business travelers from \(i\) going to \(j\) using mode \(m\) absent the CHSR. In turn, local productivities impact both wages and land rents. While changes in wages impact workers, changes in land rents are capitalized into housing values and, in this way, affect a share of residents living in each tract who are assumed to be homeowners. In the general-equilibrium extension of our model, the real-income effects of the CHSR are determined by the appendix equations A.42 and A.43.

4 Distribution of CHSR’s Local Economic Impacts

In this section, we explain the procedure we follow to estimate the parameters of the economic model described in Section 3.2. We then describe the local real income effects of the CHSR predicted by the estimated model.

4.1 Data

We conduct the analysis at the level of census tracts. Our sample covers 7,866 census tracts housing 98.5% of the statewide population. We rely on information on commuting flows from the 2006-2010 American Community Survey (ACS) (U.S. Census Bureau, 2010b) and on leisure and business trips from the California Household Travel Survey (CAHTS) (California Department of Transportation, 2012) conducted between 2010 and 2012. The CAHTS records trips longer than 50 miles over an 8-week period. To compute travel time across various transport modes, we rely on Google Maps for car and bus transit, and on official rail and air times schedules. The monetary cost of car travel is computed combining information on trip length with estimates of average driving costs per mile, while for bus, rail, and air we use information from the American Public Transportation Association (American Public Transit Association, 2010), the Bureau of Transportation Statistics (Bureau of Transportation Statistics, 2008b), and various rail operators. We construct time and monetary costs of traveling by the CHSR using information from the 2008 and 2022 CHSR business plan (California High Speed Rail Authority, 2008, 2022). We provide additional details on the data used in our analysis in Appendix B.

In addition to the estimates discussed in Section 4.2, our counterfactual predictions also rely
on tract-level information on the number of residents, labor income, land-rent income, the share of floor space used for housing, and share of local landowners (see sources in Appendix B). When computing the counterfactuals with general-equilibrium effects, we borrow spillover elasticities from the literature as detailed in Appendix B. The gravity estimates and the counterfactuals are implemented at the census tract level using data from circa 2019.\footnote{The fact that the model-implied local real-income impacts of the CHSR use data from 2019 implies that they rely on information that was not available to voters on occasion of the 2008 vote on Proposition 1A. Section 5 discusses how we account for this in our estimation of the weight that voters’ expected real-income from the CHSR had on their preferences for the CHSR.}

\section*{4.2 Gravity Estimates}

The local real income effects of the high-speed rail, as determined by (7) to (10), depend on the fraction of commuters, leisure travelers, and business travelers by origin-destination and mode ($\lambda_k(i, j, m)$ for $k = C, L, B$); the substitution elasticities $\theta_C$, $\theta_L$, and $\theta_B$; and the parameters $\rho$, $\mu_L$, and $\mu_B$. These parameters determine the preferences of the residents of each census tract for traveling to each other tract by different transport modes and, as a result, inform the extent to which these residents would modify their trip destinations and mode of transport were the CHSR to become available. We summarize here our strategy to estimate these parameters and the resulting estimates, and provide additional details in Appendix D.

\textbf{Commuting} There is a large literature estimating preferences for destinations in commuting decisions; e.g., Monte et al. (2018), Tsivanidis (2019), and Heblich et al. (2020). The specification of the worker’s commuting decision in our model, as detailed in Appendix A, enriches those baselines in three dimensions. First, we estimate preferences for modes of transport that are furthermore heterogeneous across locations of residence. Second, we account for destination- and transport-mode-specific monetary costs. Third, we allow labor income in a destination to depend on the worker’s place of residence, accounting in this way for heterogeneity in worker skill composition across origin tracts. These three elements impact the likelihood that residents of a particular census tract would use the CHSR for commuting, were it to become available.

To estimate the parameter vector $(\theta_C, \rho)$ and the commuting share $\lambda_C(i, j, m)$ for every origin, destination, and transport model, we rely on the following relationship:

$$
\lambda_C(i, j, m) = \frac{\left(\frac{I(i, j, m)}{D_C(i, m)}\right)^{\theta_C} \tau(i, j, m)^{-\theta_C \rho}}{\sum_{j' \in J} \sum_{m' \in \mathcal{M}_C} \left(\frac{I(i, j', m')}{{D_C}(i, m')}\right)^{\theta_C} \tau(i, j', m')^{-\theta_C \rho}},
$$

where $I(i, j, m)$ is disposable income (annual labor income net of monetary costs of commuting from $i$ to $j$ by transport mode $m$), $\tau(i, j, m)$ denotes the travel time between locations $i$ and $j$ by mode $m$, and $D_C(i, m)$ is a preference shifter for transport mode $m$ specific to commuters residing in location $i$. We consider three feasible modes of transport for commuting: $\mathcal{M}_C = \{\text{private vehicle, public transport, walk/bike}\}$.\footnote{All expressions in this section correspond to an equilibrium without the CHSR as defined in Appendix A.}
We perform the estimation in two steps. On the first step, we estimate \( \theta_C \) and \( \rho_C \) using a Generalized Method of Moments (GMM) estimator that exploits variation in the choice of destination conditional on origin and transport mode, \( \lambda_C (j \mid i, m) \). The estimates of \( \theta_C \) and \( \rho_C \) are thus robust to any assumption we may impose on the taste shifters \( D_C (i, m) \), which vary by origin and mode. Our estimates are \( \hat{\theta}_C = 2.97 \) (with robust standard error equal to 0.14) and \( \hat{\rho}_C = 0.75 \) (robust s.e. equal to 0.04). This last parameter captures the percentage increase in wages in a destination that would leave workers indifferent if commuting time were to increase by one percentage point. Both estimates are consistent with the literature; e.g., using tract-level data for Los Angeles, Severen (2019) estimates \( \theta_C \) to equal to 2.2; and, using county-to-county commuting data covering all of the US, Monte et al. (2018) estimate \( \theta_C \) and \( \rho_C \) to equal 3.3 and 1.3, respectively.

In the second step, we estimate \( D_C (i, m) \) for all origin census tracts and modes of transport. We model \( D_C (i, m) \) as a function of observed origin-specific demographic covariates \( X_C (i) \) with mode-specific coefficients \( \Psi_C (m) \). We estimate these coefficients using again a GMM estimator, relying on observed variation across origins with different demographics \( X_C (i) \) in their use of different transport modes. We present these estimates in Appendix Table A.1. We find that, everything else constant, residents prefer commuting by car relative to public transport, and by public transport relative to biking or walking. However, these preferences differ across census tracts, with tracts with larger shares of younger and more educated workers having a weaker preference for commuting by car, and with tracts with larger shares of nonwhite residents having a stronger preference for public transport. Importantly, the estimated values of \( D_C (i, m) \) impact usage of modes of transport in addition to the impact that commuting times and monetary costs may have.

Using the estimates \( \left( \hat{\theta}_C, \hat{\rho}_C \right) \) and the estimates of \( D_C (i, m) \) across census tracts and transport modes, using (11) we generate model-predicted commuting shares \( \lambda_C (i, j, m) \) for all origin-destination pairs and transport modes. We then use these shares in (8) to quantify part of \( \hat{W} (i) \).

**Business and Leisure Travel** The model-predicted share of business or leisure trips with origin in a census tract \( i \) and destination in \( j \) that use a mode of transit \( m \) is:

\[
\hat{\lambda}_k (i, j, m) = \frac{\left( \frac{Z_k (i, j)}{D_k (i, m)} \right)^{\mu_k \theta_k} \tau (i, j, m)^{-\rho \mu_k \theta_k} p_k (i, j, m)^{-\mu_k \theta_k - 1}}{\sum_{j \in J_k} \sum_{m \in M_k} \left( \frac{Z_k (i, j)}{D_k (i, m)} \right)^{\mu_k \theta_k} \tau (i, j, m)^{\rho \mu_k \theta_k} p_k (i, j, m)^{-\mu_k \theta_k - 1}}
\]

for \( k = L \) (leisure) or \( k = B \) (business). The shifter \( Z_k (i, j) \) captures the leisure or business appeal in census tract \( i \) of traveling to \( j \); \( D_k (i, m) \) is a preference shifter for using mode \( m \) among travelers for purpose \( k \) from \( i \); \( \tau (i, j, m) \) denotes the travel time between locations \( i \) and \( j \) by mode \( m \); and \( p_k (i, j, m) \) is the monetary cost per round trip. For both leisure and business travel, we consider three feasible modes of transport: \( M_B = M_L = \{ \text{airplane, private vehicle, public transport} \} \). Our procedure to estimate the parameters in (12) implements a two-step GMM estimator similar to that used to estimate the parameters in (11).

---

\[14\] Dingel and Tintelnot (2020) recommend using predicted shares rather than the raw observed shares to simulate impacts in quantitative spatial models, in particular in sparse settings like ours.
In the first step, we condition on the estimate of $\rho$ obtained as indicated above, and estimate $\theta_k$ and $\mu_k$ for $k = L, B$. For leisure travel, our estimate of the coefficient on log travel time, $-\mu_L \theta_L \rho$, equals -1.20 (robust s.e. equal to 0.28). The estimate of the analogous coefficient in the case of business travel, $-\mu_B \theta_B \rho$, equals -1.65. (robust s.e. equal to 0.82). As the expression in (12) illustrates, $\mu_k$ and $\theta_k$ are not separately identified. We thus calibrate $\mu_k$ using external data sources. For leisure travel, we set $\mu_L = 0.05$, consistently with BLS information on U.S. households' annual share of spending on travel, including transportation, food away from home, and lodging. For business travel, $\mu_B$ equals the share of the firm’s value added spent on its employees’ business travel. We set $\mu_B = 0.015$ following industry reports. Given these calibrated values of $\mu_L$ and $\mu_B$ and our estimate of $\rho$, the coefficients on log travel time imply estimates of $\theta_L$ and $\theta_B$ equal to 32.0 (robust s.e. equal to 7.4) and 147.0 (robust s.e. equal to 73.4), respectively. Thus, travelers perceive business and leisure destinations as highly substitutable.

In the second step, we estimate $Z_k(i,j)$ for all origin and destination census tracts by modeling these terms as a function of observed origin- and destination-specific covariates and a vector of coefficients on those covariates. Using the estimates of $\theta_k$ and $\rho$, the calibrated value of $\mu_k$, the estimates of $Z_k(i,j)$ for all origin and destination census tracts, and the expression in (12), we generate model-predicted shares of long-distance trips $\tilde{\lambda}_k(i,j,m)$, for $k = L, B$ for all origin-destination pairs and transport modes.

4.3 Alternative CHSR Scenarios

When computing the counterfactual real-income impact of the CHSR, we consider alternative scenarios in terms of the possible timeline and costs of the CHSR, summarized in Table A.2. First, we consider a “2008 Business Plan” scenario which uses the information contained in the 2008 CHSR business plan (California High Speed Rail Authority, 2008). According to this plan, the full project would be operational by 2030, tickets would be set at 50% of the corresponding airfare, and the present value of the total capital cost of implementing Phase-I of the project (linking San Francisco to Los Angeles) would be $33 billion. Second, we consider a “2022 Business Plan” scenario, which uses the information in the 2022 CHSR Update Report (California High Speed Rail Authority, 2022). According to this alternative plan, the full project would be completed in about double the number of years than forecasted in the 2008 plan, ticket prices are also doubled, and the present value of the capital costs for Phase I increase to at least $77 billion; furthermore, the

---

15 Our estimates of $\theta_C$ and $\rho$ described above imply a coefficient on log travel time of -2.24 in the case of commuting, reflecting a higher disutility of time spent traveling in the case of commuting trips than in the case of leisure and business trips.

16 The US Travel Association reports leisure travel spending in the ballpark of 800 billion USD for 2019 (U.S. Travel Association 2020 Answer Sheet), which as a share of that year's US private consumption expenditure of 14,400 billion (FRED) yields a similar share of 5.6%.

17 The US Travel Association and the Global Business Travel Association both report US business travel spending in the ballpark of 340 billion USD in 2019, which corresponds to about 1.5% of US GDP in that year.

18 This procedure allows to obtain predicted trip shares also for origin and destination tracts that are less than 50 miles away, which are not included in the CHTS survey data (see Section 4.1).
probability that the forecasts of this alternative plan are satisfied is set to only 65%.\textsuperscript{19}

For each of these two scenarios, we compute counterfactual real-income impacts using both the baseline and the general-equilibrium models described in Section 3.2. Specifically, we compute counterfactuals using (A.32)-(A.41) in Appendix A.8.

4.4 Impact of CHSR on Travel Time and Costs

An important input to determine the counterfactual impact of the CHSR is the change in travel times and monetary costs caused by the introduction of the CHSR. Appendix C details the construction of the travel times and monetary costs in the settings with and without the CHSR. In short, we calibrate a multi-modal transport network for California (including travel by car, air, bus or rail, and bike) to match observed travel times from the data. We then allow travelers to use the CHSR, and assume that it is used only when it is beneficial to do so in utility terms, given the time gain and ticket price, as described in Appendix A.6.

To put in perspective the potential time gains from the CHSR, one should note that the average commute time in California is 31 minutes one-way, with 7% of trips lasting more than 60 minutes. For leisure and business trips above 50 miles, the CAHTS shows that a quarter of Californians undertook such trips every year. Out of 64.4 million annual leisure trips, the mean trip is 143 minutes long; and out of 7.1 million annual business trips, the median is 123 minutes long. Car is the most common travel mode, used by 90% of commuters, with both public transit and walking or biking accounting each for approximately 5% of commuting trips. Travel by car accounted for 96% of leisure trips (with the remaining evenly split between air and public transit), while 88% of business trips were done by car and 10% via air.

Against this backdrop, the 2008 and 2022 CHSR business plans promised sizable potential travel time reductions. As illustrated in Table 1, if the only travelers that may use the high-speed rail were it to become available are those originally using public transit or air travel for their commute or long-distance trips (which we label as “directly impacted” travelers), then the predominance of cars as a travel model would limit severely the use of the CHSR. However, as the estimated model above indicates, the CHSR may draw travelers by altering their mode of transport (e.g., away from using the car) or the destination of their commuting, leisure or business trips. Among the directly impacted travelers, the reductions in travel time and monetary costs of the trip are substantial. For example, the median time gain for a commuter via public transit is 35%, and the median savings in monetary costs are 18%. Although these monetary gains disappear with the higher projected ticket prices updated in the 2022 Business Plan, these updated forecasts still predict large time and pecuniary gains for leisure and business travelers. The difference in the predicted monetary gains between commuters and long-distance travelers comes from the former using the relatively cheap public transit option and the latter using the more expensive air travel option.

\textsuperscript{19}As Phase-I was about 60\% of the full project, we set the cost of the total project by adjusting the capital costs proportionally to the full network. The 2022 plan expects that, by 2030, only the Central-Valley segment (180 miles) would have been completed; to obtain an expected completion date for the whole project, we extrapolate proportionally from this initial deadline.

Note: The first column shows the fraction of all travelers within each travel purpose who, before the CHSR becomes available, travels on routes where the CHSR is used when available, assuming that the CHSR may only directly replace public transit or air. The remaining columns show moments from the traveler-weighted distribution of time and cost changes across origin-destination-modes within each travel purpose, conditioning on origin-destination-modes where the CHSR is used when available.

4.5 Distribution of the CHSR Impacts across Census Tracts

We now compute the distribution across census tracts of the expected real-income effects of the CHSR, \( \hat{W}(i) \), as defined in (6). Figure 2 plots real-income effects computed using the baseline economic model and the predictions of the 2008 Business Plan, and Figure 3 zooms in on the tracts in the San Francisco Bay Area and the Los Angeles county. Bright yellow tracts gain the most, and dark blue tracts lose the most. The effects are heterogeneous. The top 10% of tracts experience real-income gains between 0.5% and 4.1% per year, while 38.7% of all tracts lose. When using instead the predictions in the 2022 Business Plan, our baseline model predicts that 92.0% of all tracts lose. Appendix Table A.3 describes the distribution of \( \hat{W}(i) \) for different model versions.

Table 2 shows regressions of the tract-level real-income changes on tract-specific characteristics in the pre-CHSR equilibrium. We regress each tract’s real-income change on its distance to the nearest CHSR station, the percentage of car and public-transit travelers, the average commute time, and fixed effects for Los Angeles county, the San Francisco Bay Area, or the Central Valley. The estimates unveil several patterns. First, tracts closer to stations gain more. Second, tracts with lower car usage, a higher usage of public transportation, or longer commute times gain more, as these tracts are more likely to adopt the CHSR. Third, tracts located in Los Angeles county or in the San Francisco Bay Area gain more than what the regression covariates would predict; in contrast, Central Valley locations like Fresno or Bakersfield gain less. These location-specific results illustrate the importance of accounting for the specific travel patterns of different regions of California.

The similarity of the estimates displayed in the different columns in Table 2 suggests that the distribution in space of the real-income gains of the CHSR is very similar regardless of whether we incorporate general-equilibrium forces in the model, and regardless of whether we model the CHSR according to the 2008 or the 2022 projected costs, travel speed, and ticket prices. However, the
level of the implied gains varies significantly depending on whether we incorporate in our analysis the predictions of the 2008 Business Plan or those of the 2022 Plan. In our baseline model, we obtain aggregate (i.e., population-weighted) gains of 0.16% using the projections in the 2008 Plan, and mean losses of -0.21% using the projections in the 2022 Plan, as shown in the last column of Appendix Table A.3. \(^\text{20}\)

\(^{20}\)There are many differences in method, underlying data, and details of implementation between our analysis and existing cost-benefit analyses of the CHSR. Still, we can broadly compare the ballpark of our numbers against existing

</tbody>
</table>

Note: The table shows the result from running, for each model variant, an OLS regression of the tract-level real-income change, \( \hat{W}(i) \), on observable tract characteristics. “dist. to station” is the tract centroid’s distance to the nearest CHSR station, “% public transit” and “% car” are the fraction of residents who initially commutes via public transit or via car, and “commute time” is the average commuting time by road. The LA, SF and CV fixed effects correspond to dummies for whether the census tract is within LA county, one of the SF bay area counties or one of the 18 Counties of the Central Valley, respectively.

Appendix table A.4 further decomposes the aggregate effects into those stemming from commuting, leisure travel, and business trips. Without general-equilibrium effects, commuting account for almost all of the aggregate effect – even though long-distance leisure trips save more time than the average commute trip, aggregate commuting time dwarfs leisure travel time. The magnification of gains in the case with general-equilibrium impacts are due almost exclusively to the productivity-enhancing effects of business trips.

5 Effect of Local Economic Impacts on Votes

Armed with the estimated model of the real-income gains of the CHSR, we now estimate the parameter \( \theta_V \) in (4), which determines the impact of expected real-income in shaping voters’ preferences for the CHSR.

estimates that have considered related forces. Initial 2008 estimates by the High-Speed Rail Authority (California High Speed Rail Authority, 2008) estimated net present-discounted gains of $97bn in 2008 USD. In our baseline, the analog number is $69.9bn. The 2022 CHSR project update (California High Speed Rail Authority, 2023) includes a benefit-cost analysis such that, if only “high-speed rail user benefits” are included (corresponding to the forces we include in the case without indirect effects), the phase-I of the CHSR (from San Francisco to Los Angeles and Anaheim) leads to a present-discounted loss of $15bn in 2021 dollars. Our 2022 scenario without GE can be compared to this estimate, although it implements the full CHSR (instead of just phase-I) by scaling up costs in proportion to the additional miles of the total network relative to phase-I. This scenario yields a loss of $-91.6 bn in 2021 USD. The 2023 CHSR update also reports gains of $26bn for the Phase I when “wider economic benefits for worker and firms” are further included in addition to rail user benefits. These can be compared with our estimates including indirect effect for the 2022 case. These still correspond to a loss, although lower: $-76.2 bn for the full network.
5.1 Estimation Strategy

When estimating voters’ response to expected real income in the 2008 referendum, two potential identification issues arise. First, we may measure voters’ expected real-income gain from the CHSR with error. Second, there may be other determinants of voters’ CHSR preferences that are correlated with their expected real-income gain from the CHSR. While the first is an instance of measurement error in the covariate of interest, the second is an example of omitted variables correlated with that covariate. We discuss here these identification concerns and the strategies we follow to address them.

**Measurement Error**  We do not observe voters’ expectations of the CHSR’s real income impact, $E[\ln \hat{W}(i) | I_i]$ in (4). Instead, we identify $\theta_V$ as the coefficient on the model-implied ex-post real income impact of the CHSR, which we thus use as proxy for voters’ expectations; i.e., our proxy is $\ln \hat{W}(i)$, as defined in (6) and computed using the estimates described in Section 4.5. Because this proxy is constructed using information on realized fundamentals (such as productivities) from 2019, we denote it in this section by $\hat{W}_{19}(i)$. Without loss of generality, differences between voters’ expectations and this proxy may be decomposed into two terms: (a) voters’ expectational error, denoted by $\epsilon_{W,1}(i)$; and, (b) model misspecification, i.e., any mismatch between the true ex-post CHSR impact and that predicted by our model, denoted by $\epsilon_{W,2}(i)$. Thus, we can write:

$$E[\ln \hat{W}(i) | I_i] = \ln \hat{W}_{19}(i) - \epsilon_{W,1}(i) - \epsilon_{W,2}(i).$$

(13)

If voters’ expectations are rational, the error $\epsilon_{W,1}(i)$ is analogous to classical measurement error, biasing OLS estimates of $\theta_V$ towards zero. Any IV estimator that uses as instrument a variable that belongs to voters’ information set at the time of the vote avoids this source of bias (Dickstein and Morales, 2018). We present below estimates that use as such instrument the model-implied real-income impact of the CHSR constructed using fundamentals from 2008, denoted by $\ln \hat{W}_{08}(i)$. If voters’ expectations are rational and the 2008 fundamentals belong to their information sets, this instrument will be mean independent of the expectational error $\epsilon_{W,1}(i)$. If, furthermore, our model were to correctly capture the ex post economic impact of the CHSR, then the resulting IV estimator of $\theta_V$ would be unaffected by measurement error.

Importantly, rationality of expectations is sufficient but not necessary for our IV estimator of $\theta_V$ to avoid measurement error bias. As discussed below, when estimating $\theta_V$, we condition on a set of controls, one of them being the share of registered Democrats in each census tract. Thus, our IV estimator of $\theta_V$ is not affected by voters’ expectational errors even if voters have biased beliefs about the real income impact of the CHSR, as long as the bias in expectations aligns with their party affiliation.

Characterizing the bias due to the model misspecification error $\epsilon_{W,2}(i)$ is more complicated, as it depends on which particular model aspect is inaccurate. We address this potential bias by exploring how robust our estimates of $\theta_V$ are to the alternative economic models described in Table A.2. As a reminder, models differ in the projected CHSR capital costs (they either use the
projections in the 2008 or the 2022 Business Plan) and in the economic forces incorporated in the model (they either abstract from or incorporate general-equilibrium effects).

**Omitted Variables** The determinants of voters’ preferences entering through the component \( \hat{a} (i) \) in (4) may be correlated with voters’ expectations of the CHSR’s real income impact. To limit the risk that our estimates of \( \theta_V \) suffer from omitted variable bias, we introduce proxies for subjective considerations that may play a role in voters’ preferences for the CHSR. Formally, we assume that:

\[
\ln \hat{a} (i) \equiv \sum_{k=1}^{K} \tilde{\beta}_k X_k (i) + \epsilon_a (i) .
\]  

(14)

We introduce three sets of covariates \( X_k (i) \). The first set proxies for voters’ ideology: it includes the tract-specific share of registered Democrats and the tract-specific vote shares in favor of two propositions, Prop. 10 and Prop. 1B, on clean energy and transportation projects, respectively.\(^{21}\) We interpret the vote share in support of Prop. 10 as a proxy for voters’ environmental concerns, and the vote share in support of Prop. 1B as a proxy for voters’ willingness to back transportation infrastructure spending in general. The second set of covariates measures demographic characteristics: the tract-specific share of residents who are nonwhite, college-educated, or under 30. Finally, the third set of covariates measures the time it would take voters in each tract to reach the closest CHSR station. This distance measure accounts for any correlation between the location of the CHSR stations and voters’ CHSR preferences that is not captured by the two other sets of covariates.\(^{22}\) In addition to these covariates, we control in all specifications for county fixed effects. Consequently, the identification of \( \theta_V \) is based on variation across census tracts within counties.

We conceptualize all these political, demographic, and proximity covariates, as well as the county fixed-effects, as controls that help us obtain consistent estimates of \( \theta_V \). The interpretation of the coefficients on these covariates is not relevant for our purpose; those coefficients may capture the impact of multiple treatments and, thus, may have multiple valid interpretations. For example, the share of registered Democrats in a tract may capture both differences in CHSR preferences driven by political ideology and differences in beliefs about the future real income impact of the CHSR.

**Instrument #1: Random Stations** The covariates \( X_k (i) \) described above, together with \( \ln \hat{W}_{19} (i) \), account for a large share of the variation in vote shares across locations.\(^{23}\) All deter-

\(^{21}\)Prop. 10 (“Bonds for Alternative Fuels Initiative”), on the ballot at the same time as the CHSR, asked voters to authorize the government of CA to issue $5 billion in bonds for alternative fuel projects (it failed with 40.6% of votes in favor). Prop. 1B (“Transportation Bond Measure”), on the ballot in 2006, asked voters to authorize the government of CA to issue $19.9 billion in bonds for transportation projects (it passed with 61.4% of votes in favor). Source: ballotpedia.org.

\(^{22}\)Note that \( \ln \hat{W} (i) \) accounts for preferences for using different means of transport (car, public transit, airplane, or biking), as described in Section 4.2. Thus, the measure of distance to the projected CHSR stations included among the set of controls captures any effect on CHSR preferences of being close to CHSR stations other than the potential usage of the CHSR were it to become available, which enters through \( \ln \hat{W} (i) \).

\(^{23}\)The R-squared of the OLS estimated regression is above 0.9 in the specification with the largest set of covariates.
minants of voters’ CHSR preferences not controlled for by these covariates are accounted for by the term $\epsilon_a (i)$ in (14). If these omitted variables are correlated with the model-implied CHSR income impact, $\hat{W}_{19} (i)$, the OLS estimate of $\theta_V$ will be biased. If they are also correlated with the model-implied impact when fundamentals are set to their 2008 values, the TSLS estimate of $\theta_V$ that uses $\ln \hat{W}_{08} (i)$ as an instrument will also be biased.

Thus, we also present TSLS estimates of $\theta_V$ that rely on an alternative instrument that we build as follows: in a first step, we simulate one hundred counterfactual CHSR networks by randomizing the location of 24 stations along the projected CHSR railway line; in a second step, for each of these counterfactual networks and all census tracts, we compute the associated model-implied real-income change using 2008 fundamentals; finally, in a third step, we compute the average of these real income changes across the one hundred simulated networks. More specifically, denoting the instrument by $\hat{W}_{08}^{IV} (i)$, we build it as:

$$
\hat{W}_{08}^{IV} (i) = \frac{1}{100} \sum_{n=1}^{100} \ln \left( \hat{W}_{08}^{cf} (i, n) \right),
$$

(15)

where $\hat{W}_{08}^{cf} (i, n)$ is the model-predicted change in welfare in location $i$ from the counterfactual CHSR design $n$ built using 2008 fundamentals.

**Instrument #2: Random Stations and Random Paths** We construct a second instrument where, instead of randomizing the location of stations along the projected CHSR railway line, we use information on three alternative railway lines that were considered in the early stages of the CHSR design process (US DOT, 2005); see Appendix Figure A.1. Relevant for the validity of this second instrument, these three alternative CHSR routes were selected as candidates to link Los Angeles to San Francisco on the basis of technical feasibility and cost savings.\(^{24}\) Thus, political considerations may have determined the final choice between the three alternative routes (and the location of the 24 stations), but they were not behind the decision to limit the set of possible routes to these three alternative railway lines. Hence, our second instrument uses the formula described in (15), where each counterfactual CHSR design $n$ is determined by first drawing randomly one of these three potential routes, and then randomly locating the 24 stations along that route.

As these two instruments incorporate information on neither the actual location of the 24 projected stations (in the case of the first instrument) nor on the actually projected CHSR railway line (in the case of the second instrument), they may be valid even if the location of the CHSR stations (or the railway line, in the case of the second instrument) had been determined with the goal of favoring tracts with systematically larger or smaller values of the unobserved term $\epsilon_a (i)$. Moreover, as the instruments only use information on 2008 fundamentals, they will be mean independent of the expectational error $\epsilon_W (i)$ under the conditions discussed above.

\(^{24}\)There are two possible routes from Northern to Southern California: along the coast or through the center of the state (along the I-5 highway or via the Central Valley). The topology of the coastal area makes it more difficult for trains to reach top speed and is costlier in terms of building. Along the I-5, the terrain is flatter and construction is cheaper but the stations are farther away from population centers. The third option, via the Central Valley, ranks in between these alternatives in terms of both proximity to population and expected costs.
5.2 Estimates of Voter Preferences

Combining (14) with (13) and (4), we obtain our estimating equation:

\[
\ln \left( \frac{v(i)}{1 - v(i)} \right) = \theta_V \ln \hat{W}(i) + \sum_{k=1}^{K} \beta_k X_k(i) + \epsilon(i),
\]

where \( \beta_k \equiv \theta_V \tilde{\beta}_k \) and where \( \epsilon(i) \equiv \theta_V (\epsilon_a(i) - \epsilon_{W,1}(i) - \epsilon_{W,2}(i)) \) includes unobserved components of voters’ preferences, measurement error, and model misspecification error. In Table 3, we report OLS and TSLS estimates of \( \theta_V \) and the \( \beta_k \)’s. In this table, we compute the real-income impact of the CHSR using the baseline economic model (without general-equilibrium effects) and the projections included in the 2008 Business Plan (we discuss alternative specifications below). In the first four columns, we present OLS estimates for regression specifications that progressively account for a larger set of regressors. In column (1), we include no covariate other than the model-implied welfare impact of the CHSR. In column (2), we add proxies for political ideology; in column (3), we add variables that capture the demographic composition of the residents of each census tract; and, in column (4), we add as a control the log of the shortest time distance from each tract to its closest station.

The estimated value of \( \theta_V \) equals 15.13 (with robust s.e. equal to 1.09) in the specification with the largest set of controls. This estimate of \( \theta_V \) is robust to whether we control for voters’ demographic characteristics or by the distance to the closest HSR station. The estimates of the coefficients on the various controls reveal that a larger support for the CHSR is predicted by the following census tract characteristics: a larger share of registered Democrats; a larger support for Prop. 10 (support for alternative fuel vehicles); a larger support for Prop. 1b (support for transportation projects); a larger share of residents who are white, college-educated, or under 30 years of age; and proximity to a CHSR station.

Columns (5) to (7) report IV estimates. Column (5) uses as instrument the 2008-based real income measure, column (6) uses the instrument that additionally randomizes the location of the stations alone, and column (7) uses the instrument that additionally randomizes the location of both the railway line. For the three instruments we obtain large first-stage F-statistics.

The estimate of \( \theta_V \) increases progressively as we move from column (4) to (7). The fact that the IV estimate of \( \theta_V \) that uses as instrument the 2008-based real income measure is larger than the OLS estimate (17.96 vs. 15.13) is consistent with the latter being downward biased due to voters’ expectational errors. The fact that the IV estimates of \( \theta_V \) computed using both the random-station and the random-path instruments are larger than that reported in column (5) reveals that the CHSR design favored census tracts whose residents were, for unobserved reasons, less predisposed to support the proposed CHSR.

Results across Model Variants  Appendix Table A.5 presents analogous estimates to those in columns (6) and (7) in Table 3, but using the alternative model variants described in Table A.2. The estimates of \( \theta_V \) are larger under the costs and timeline projections from the 2022 Business Plan than under the projections in the 2008 Plan. Intuitively, this happens because there is a high

F-stat: 1197 \(\text{Num. Obs.} = 7861\) 672 466

Note: \(^a\) denotes 1% significance level. Robust standard errors in parenthesis. All specifications control for county fixed effects.

correlation across tracts (greater than 95.9%) in the economic impacts predicted by the two model variants, but the variance of these tract-specific predictions is smaller when using 2022 information, resulting in a larger \(\theta_V\). Conversely, the estimates of \(\theta_V\) are smaller when the CHSR real-income impacts are computed using the model that incorporates general-equilibrium impacts; that model yields a distribution of \(\ln \hat{W}(i)\) that is very correlated with that predicted by the model without general equilibrium effects, but more dispersed, resulting in a smaller estimate of \(\theta_V\).

Robustness Our estimates are robust to a range of alternative weighting schemes and sample selection criteria. Appendix Table A.6 presents estimates analogous to those in columns (6) and (7) in Table 3 but for specifications that weight the results in each tract by either the total number of votes (in columns (3) and (4)) or by the participation rate (in columns (5) and (6)). When implementing either of these two weighting schemes, we obtain IV estimates of \(\theta_V\) that are slightly larger than the baseline (unweighted) estimates reported in Table 3. Columns (7) and (8) in Appendix Table A.6 show that the estimates of \(\theta_V\) are minimally affected when we redo our estimation dropping the nearly 3,000 census tracts that are less than 5km away from the railway line.

\(^{25}\)The belief \(p\) that the CHSR will be successfully completed enters the calculation of \(\ln \hat{W}(i)\) by multiplying the per-period economic effects \(\ln \hat{V}(i)\), as shown in equation (6). Hence, a lower \(p\), reflecting the more pessimistic beliefs included in the 2022 Business Plan, leads to lower variance of \(\hat{W}(i)\).
5.3 Implications

The estimates discussed above imply we cannot reject the joint hypothesis that voters in the 2008 referendum cared about the expected real income impact of the CHSR, and that this variable is correlated with our model predictions. The estimates thus provide support for our estimated model as a predictor of the spatial distribution of the real-income effects of the CHSR. They further illustrate that economic voting was a driver of policy preferences over the CHSR. While economic voting has been shown to be a strong driver of votes in electoral politics (Lewis-Beck and Stegmaier, 2000), this not the case regarding changes in transport systems, with case studies and survey evidence suggesting low public support for transport policies with seemingly positive net economic impacts. In contrast, using data on actual votes, we show that changes in the expected economic impact of the CHSR had a significant effect on voters’ preferences.

Our estimates also determine the additional real income needed to sway votes. Consider an alternative CHSR design that would have increased expected economic gains in location $i$ by $d\hat{W}(i)$ percentage points, compared to $\hat{W}(i)$ in the actual CHSR design. This change would have affected the favorable votes in location $i$ by

$$dv(i) = \frac{\theta_v v(i)(1-v(i))}{\hat{W}(i)}d\hat{W}(i)$$

percentage points. Table 4 uses this formula to compute the real income change needed to sway an extra percentage point of votes in favor of the CHSR around an equilibrium with the actual CHSR design. Across model variants, an extra 0.1-0.2 percentage points in expected economic gains sway one percentage point of local votes in the median tract; to put this number in perspective, the standard deviation of favorable votes across census tracts was 0.1 percentage points, and that of expected real income gains was in between 0.2 and 0.4 percentage points. Given the economic significance of this magnitude, we conjecture that policymakers could have decided to allocate stations based on their impact on public support, at the expense of locations where stations were socially more desirable. We quantify this trade-off in the next section.

Note: The $\theta_v$ reported corresponds to IV estimate using the random routes instrument shown in Table 3. The second column reports the 50th percentile of the distribution across tracts of the inverse of $\theta_v v(i)(1-v(i))/\hat{W}(i)$ in (17). This inverse measures the real-income gains required to sway 1% of votes around the equilibrium with the CHSR.

---

26 An example is road pricing; see Verhoef et al. (1997), Schade and Schlag (2003), and Noordegraaf et al. (2014).
6 Policymakers’ Preferences and Optimal Designs

We consider the problem of a planner who decides where to locate the CHSR stations. This problem captures, in reduced form, a complex process leading up to the referendum involving politicians and technical experts. Rather than modeling this process, we propose an “as if” representation, in which a hypothetical planner has preferences over the welfare of residents of different locations and over votes. We estimate the preferences of such social planner, identifying as a result the distributional biases emerging from this complex process.\footnote{In the context of models of tariff formation, Baldwin (1987) points out that different underlying political economy models can map to a planner’s problem with group-specific weights; Grossman and Helpman (1994) model a political game with lobby contributions that can be represented by a planner’s problem with sector-specific Pareto weights; and Adão et al. (2023) estimate the Pareto weights across industries and skill groups of a hypothetical planner setting US tariffs.}

Section 6.1 sets up the planners’ problem, Section 6.2 discusses how we estimate the planner’s preferences, and Section 6.3 solves for optimal station allocations with counterfactual planner’s preferences.

6.1 Planner’s Problem

To set up the planner problem, one could use an approach in the spirit of Fajgelbaum and Schaal (2020) or Kreindler et al. (2023), where the planner is charged with designing an entire network with full flexibility over its design. In our case, this would amount to deciding both the location of the railway lines and of the stations along these lines. Doing so raises methodological challenges due to dimensionality, and would also imply the need to model and quantify the potentially heterogeneous costs of building rail lines at different locations.

Leveraging the fact that only three alternative routes were identified as being feasible on the basis of cost and engineering considerations, we restrict the planner’s problem to choosing the preferred route and the location of stations along such routes. More specifically, the CHSR was originally meant to connect Los Angeles and San Francisco, further branching to San Diego and Sacramento in later phases. As discussed in Section 5.1, three possible routes linking Northern and Southern California were originally identified (US DOT, 2005): one ran along the coast, and the other two ran through the center of the state, either along the I-5 highway or through the Central Valley (see Appendix Figure A.1). The coastal route was quickly discarded due to much higher costs, leaving the I-5 and the Central Valley routes as the main options for policymakers to choose between. Therefore, we model the planner as deciding which of these two routes to use, and where to place the stations along the chosen route.

Formally, the planner chooses the geographic coordinates $d = \{d_1, \ldots, d_{24}\}$ of the 24 CHSR stations, where each $d_i$ belongs to a set $\mathcal{D}$ of feasible coordinates. Each design $d$ maps to a distribution of travel times and travel costs. Hence, each $d$ maps to a utility level of each agent $\omega$ if the design is approved ($u_\omega(Y; d)$ defined in (1)), and to a share of favorable votes ($v(i; d)$ defined...
in (4)). Specifically, the planner’s valuation for design \( d \) given a realization of fundamentals is:

\[
W(d) \equiv \sum_{i=1}^{I} \lambda_U(i) N_R(i) \mathbb{E}_\omega [u_\omega(Y;d) - u_\omega(N)] + \lambda_V \sum_{i=1}^{J} N_R(i) v(i;d).
\]  

(18)

The first term in (18) is a weighted sum across tracts \( i \) of the average (over agents \( \omega \) living in \( i \)) expected utility gains from the CHSR being approved. This sum uses location-specific per-capita weights \( \lambda_U(i) \) that capture the planner’s preferences for each of the \( N_R(i) \) residents of tract \( i \). Thus, this term captures distributional impacts among constituencies. We define the \( \lambda_U(i) \) as functions of observed covariates \( Z_k(i) \) (including a constant, \( Z_0(i) \equiv 1 \)):

\[
\lambda_U(i) \equiv \sum_{k=0}^{K} b_k Z_k(i).
\]  

(19)

The second term in (18) is the total number of votes in favor of the CHSR; when \( \lambda_V > 0 \), the planner attaches a positive weight to favorable votes. Thus, this term captures that policymakers may take into account the popular approval elicited by a transport infrastructure project.

The design \( d^0 \) that maximizes the planner’s objective function in (18) is:

\[
d^0 = \arg \max_{d \in \mathcal{D}} \mathbb{E}[W(d)],
\]  

(20)

where the expectation is taken over future realization of the economic fundamentals, unknown at the time of designing the CHSR. Using the definition of \( u_\omega \) in (1), and assuming voters’ information about fundamentals at the time of voting is as rich as the planner’s, the optimal design is

\[
d^0 = \arg \max_{d \in \mathcal{D}} \mathbb{E}\left[ \sum_{i=1}^{J} \lambda_U(i) N_R(i) \ln \hat{W}(i; d) + \lambda_V \sum_{i=1}^{J} N_R(i) v(i; d) \right].
\]  

(21)

Similar to voters, we assume the planner has rational expectations. Hence, for any design \( d^n \) different from the optimal design \( d^0 \):

\[
\mathbb{E}\left[ W(d^n) - W(d^0) \right] \approx \sum_{i=1}^{J} \left( \lambda_U(i) + \lambda_V \frac{\partial v(i)}{\partial \ln \hat{W}(i)} \right) N_R(i) \Delta \ln \hat{W}(i, d^n) - \epsilon(d^n) \leq 0,
\]  

(22)

where

\[
\Delta \ln \hat{W}(i, d^n) \equiv \ln \left( \frac{\hat{W}(i; d^n)}{\hat{W}(i; d^0)} \right) = \ln \left( \frac{W(i, Y, d^n)}{W(i, Y, d^0)} \right)
\]  

(23)

is the log difference between the real income generated by the design \( d^n \) and that generated by the optimal design \( d^0 \), and where \( \epsilon(d^n) \) is the planner’s expectational error when evaluating the impact of the high-speed rail design.

### 6.2 Estimation of Planner’s Preferences

We assume that the observed CHSR design corresponds to the optimal choice of the planner. Thus, according to (22), any deviation from the observed design must yield weakly negative returns. Condition (22) demonstrates how the trade-off between votes and real income in the planner’s design helps us identify the planner’s preferences. The planner has incentives to favor locations with higher Pareto weight \( \lambda_U(i) \) or higher returns in terms of votes, as captured by \( \partial v(i) / \partial \ln \hat{W}(i) \) defined in
Unchosen CHSR designs that increase the real income of a location \( i \) at the expense of some other location \( i' \) reveal an upper bound for \( \lambda_U(i) \) relative to \( \lambda_U(i') \). Similarly, unchosen CHSR designs that increase (reduce) aggregate (\( \lambda_U \)-weighted) real-income while reducing (increasing) aggregate votes reveal a lower (upper) bound for \( \lambda_V \) relative to the average of the \( \lambda_U(i) \)’s.

A possible approach to estimate the parameters entering (18) would be to exploit differences in the planner’s payoff function in reaction to small perturbations to stations’ locations, much like Goldberg and Maggi (1999) and Adão et al. (2023) do for tariffs. In that case, we could derive moments from the first-order condition in (22) holding as an equality rather than as an inequality. However, in our empirical setting, this approach has little identification power due to all covariates of interest changing smoothly in space. Moreover, closed-form solutions for optimal policies, which are relied upon for implementation in the previous papers on tariffs, are unavailable in our case. Instead, we use a moment inequality estimator that exploits discrete (rather than marginal) deviations from the planner’s observed station placement, in which case we can construct moments from the first-order condition in (22) holding as a weak inequality. Specifically, we derive our moment inequalities following the revealed-preference approach introduced in Pakes (2010) and Pakes et al. (2015). We provide implementation details in Appendix F.

The main shortcoming of our estimator is the absence of unobserved (to the researcher) determinants of the planner’s payoff function (e.g., cost shocks) that may vary across locations. Allowing for such unobserved determinants in our setting would only be feasible if we could determine ex ante (i.e., for all parameter values) whether the decisions to place stations in any two locations are complements or substitutes (see, e.g., Jia (2008), Arkolakis et al. (2023), and Castro-Vincenzi et al. (2024)). Unfortunately, in our setting, those decisions may be either complements or substitutes: depending on the placement of other stations, the planner’s gains from an extra station may decrease or increase as stations are added. Therefore, to implement our moment inequalities, we must model the unobserved terms as expectational errors of the planner (see Jeon and Rysman (2024) for a similar approach).

**Construction of Perturbations and Moments** To build the inequalities in (22), we first construct hundreds of perturbations to the distribution of stations along the proposed CHSR design. In each perturbation, one station is shifted to another location without a proposed station. The set of alternative locations is chosen to identify upper and lower bounds on the parameters: we use the peaks and troughs of the covariates \( Z_k(i) \) and of the voting elasticity \( \partial v(i) / \partial \ln \hat{W}(i) \) along the CHSR rail line.\(^{28}\) We index each one-station deviation by \( n \) and let \( d^n \) be the associated design.

Figure 4 shows one such perturbation, where the station in downtown LA is shifted towards Anaheim. The map on the left shows the real-income differences with the actual design, \( \Delta \ln \hat{W}(i) \) in (23). The map on the right shows the voting semi-elasticity, \( \partial v(i) / \partial \ln \hat{W}(i) \). Downtown LA is a low-voting-gradient area as it strongly supports the CHSR, so increasing their residents’ real income barely changes votes in that location. Conversely, the areas closer to the new location.

\(^{28}\)Figure A.2 in Appendix F shows such peaks and troughs for a covariate \( Z_k(i) \) that equals population density.
the figures show the $\Delta \ln \hat{W}(i)$ for a specific perturbation using 2008 cost predictions, and the voting semi-elasticity at the initial equilibrium corresponding to our preferred estimate under those cost predictions.

of the station have higher voting elasticities with respect to real income. Thus, by shifting the station’s location, this perturbation redistributes real income from low-voting-gradient areas of LA to higher-voting-gradient places in Orange County. As this perturbation implies a reduction in the real-income component of the planner’s objective and an increase in aggregate votes, it helps identify an upper bound on the preference for votes $\lambda_V$ relative to an average of the $\lambda_U(i)$.

For estimation, we build moment inequalities using mutually exclusive subsets of perturbations. Specifically, letting $\mathcal{N}$ be the set of all perturbations, each moment $e = 1, \ldots, E$ is defined as the average value $m(\mathcal{N}_e)$ of the perturbations to the planner’s objective, $\Delta W(d^n)$ defined in (22), across a subgroup $\mathcal{N}_e \subset \mathcal{N}$:

$$m(\mathcal{N}_e) \equiv \sum_{n \in \mathcal{N}_e} \Delta W(d^n) \leq 0 \quad (24)$$

for $e = 1, \ldots, E$. As long as the subsets $\mathcal{N}_e$ are defined as a function of variables that belong to the information set of the planner, the assumption of rational expectations implies that the expectational errors $\epsilon(d^n)$ in (22) are averaged out in $m(\mathcal{N}_e)$.

Then, using (19), we can rewrite the moment inequality $e$ in (24), as

$$m(\mathcal{N}_e) \equiv \sum_{n \in \mathcal{N}_e} \left[ \sum_{k=0}^{K} b_k Z_k(i) + \lambda_V \theta_V v(i) (1 - v(i)) \right] N_R(i) \Delta \ln \hat{W}(i, d^n) \leq 0 \quad \text{for } e = 1, \ldots, E. \quad (25)$$

---

29I.e., $\sum_n \epsilon(d^n) 1 \{n \in \mathcal{N}_e\} \to 0$ as $\sum_n 1 \{n \in \mathcal{N}_y\} \to \infty$. This result depends on two assumptions. First, for any perturbation $n$, the unobserved term $\epsilon(d^n)$ is unknown to the planner at the time at which the optimal CHSR design was chosen; this is guaranteed by the assumption that $\epsilon(d^n)$ exclusively incorporates expectational errors of the planner. Second, across the perturbations $n$ included in the same subset $\mathcal{N}_e$, the correlation across the different unobserved terms $\epsilon(d^n)$ is sufficiently low such that the Law of Large Numbers applies.
The inequalities in (25) provide $E$ conditions that depend on observable covariates $(Z_k(i), v(i)(1 - v(i)), N_R(i))$, the model-generated real-income gains in each perturbation $\hat{W}(i, d^a)$, and the previously estimated $\theta_V$. Using these $E$ conditions, we recover the $K + 2$ parameters $b_0, ..., b_K$ and $\lambda_V$. We group perturbations that help identify upper and lower bounds for our various parameters (see Appendix F.1 for details). Because the conditions hold as inequalities, we compute confidence sets for the parameters $\{b_k, \lambda_V\}$ following Andrews and Soares (2010). This procedure identifies an admissible set of parameter values such that, for a given confidence level, we are unable to reject the hypothesis that the data was generated by a parameter vector within the set.

**Pareto Frontier Between Votes and Welfare** To understand how we form the moment inequalities and how they identify our parameters, we discuss here a restricted case in which the planner has no preferences over the distribution of real income in space (the planner’s objective function has $b_k = 0$ for $k = 1, ..., K$). Instead, it holds preferences over a utilitarian component of real income, $\sum N_R(i) \ln \hat{W}(i, d)$, and over aggregate votes, $\sum N_R(i) v(i; d)$, with weights $b_0$ and $\lambda_V$, respectively. Because only $\lambda_V/b_0$ is identified, we normalize $b_0 \equiv 1$. Figure 5 plots all the perturbations, where the x-axis represents the (demeaned) total change in votes and the y-axis represents the change in the utilitarian component of the planner’s welfare. The actual CHSR proposal corresponds to the point $(0, 0)$.

As the only unknown parameter is $\lambda_V$, we form four moments $m(\hat{N}_v)$ by grouping the perturbations according to how they fall in the four quadrants displayed in the figure. The lower-left quadrant groups perturbations that yield both lower utilitarian welfare and lower votes than the actual CHSR proposal, trivially satisfying our inequality conditions. In turn, perturbations in the
upper-right quadrant imply greater welfare and higher votes, and can only be rationalized by the planner’s expectational errors.

In contrast, the perturbations in the upper-left and lower-right quadrants suggest a trade-off between welfare and votes. The orange dots represent the two moments $m(N_e)$, that average across all perturbation within the corresponding quadrant. The values for $\lambda_V$ (relative to $b_0$) consistent with these two moment inequalities are those that satisfy the condition $y + \lambda_V x \leq 0$, with $(x, y)$ the coordinates of each of the two moments depicted in the orange dots. Visually, this set corresponds to drawing a line through the origin with (negative) slopes $x_{UL}/y_{UL}$ and $x_{LR}/y_{LR}$ (where $UL$ and $LR$ denote the upper-left and lower-right quadrants, respectively) and taking the intersection of the areas between these lines, as represented by the purple area on the graph. The set is $0 \leq -x_{UL}/y_{UL} \leq \lambda \leq -x_{LR}/y_{LR}$.

As the figure illustrates, the perturbations in the upper-left quadrant identify a strictly positive lower bound on $\lambda_V$, while those in the lower-right quadrant identify an upper bound. Our estimation procedure extends this logic to multiple covariates. Appendix F gives additional details on how the perturbations and moments are constructed in the general case in which the unknown parameter vector includes $b_k$ for $k = 1, \ldots, K$, and on how we implement the procedure in Andrews and Soares (2010) to compute confidence sets.

Parameter Estimates

Table 5 shows estimates of the $b$’s and $\lambda_V$ under the baseline model using the projections contained in the 2008 Business Plan. We present results for specifications that allow the planner’s Pareto weights to depend on population density, the share of college-educated residents, or the share of non-white residents. In the estimation, the parameter space is not restricted and, as a result, our confidence sets could include both positive and negative values for each parameter $b_k$ or $\lambda_V$.

To simplify the interpretation, we standardize every covariate $Z_k(i)$ and normalize to 1 the population-weighted mean of the Pareto weights $\lambda_U(i)$. Each parameter $b_k$ can thus be interpreted as capturing the impact of a one-standard deviation increase in $Z_k(i)$ relative to the average Pareto weight.\footnote{We also demean the variable $\theta_v v(i) (1 - v(i))$. As a result, the constant we estimate is $b_0 + \lambda_V \mathbb{E} [\theta_v v(i)(1 - v(i))]$ and captures the overall utilitarian motive of the planner, including what is inherited from the voting block.} For each specification and parameter, we report the 95% confidence set projected on the corresponding parameter. Column (1) of Table 5 corresponds to Figure 5. Columns (2) to (4) allow for one $b_k$ at a time, while column (5) reports an estimation with all the $b_k$’s.

Regardless of the specification of the Pareto weights, our estimates indicate the planner has a strictly positive preference for votes. The confidence sets for the parameters entering the planner’s Pareto weights indicate that the planner assigns a larger weight to welfare in census tracts with a larger share of college-educated residents, but we cannot rule out that these weights are invariant to the census tract’s population density and share of non-white residents. Since the $\lambda_U(i)$ are defined as per-capita Pareto weights, the planner assigns a larger weight to average utility in more populated tracts even if the per-capita Pareto weight does not vary with population density.

Appendix Figure A.4 shows the distribution of total Pareto weights $\lambda_U(i) + \lambda_V \theta_V v(i) (1 - v(i))$ across tracts $i$ implied by the centroid of our confidence set. The estimates imply a large variance in the Pareto weights, indicating that the planner is far from the utilitarian benchmark.

Table A.7 in the Appendix repeats the estimation using the projections in the 2022 Business Plan. We find that the estimates of the planner’s weights are robust: the values of the $b_k$’s are unchanged, while both bounds of $\lambda_V$ remain positive, although rescaled due to the different magnitude of welfare gains and our different estimate for $\theta_V$.

6.3 Optimal Station Placement with Apolitical Preferences

To illustrate the importance of political and distributional considerations for the design of transportation policy, we compute the optimal station placement for planners with different preferences. The optimal station placement problem is non-convex due to the existence of substitutabilities and complementarities across stations, as well as due to the sigmoidal function –neither convex nor concave– that defines the voting probabilities $v(i; d)$. For implementation, we use a three-step optimization procedure that combines the perturbations from the estimation stage, simulated annealing, and a continuous optimizer. Appendix F.2 provides additional details.31

Optimal Stations Along the Actual CHSR Design We compare the proposed CHSR design to that preferred by an apolitical planner whose objective function does not depend on votes (i.e., $\lambda_V = 0$), thereby eliminating the planner’s incentives to assign higher real income to higher voting-elasticity locations. We set the values of the remaining parameters entering the planner’s Pareto weight to the centroid of the confidence sets from column (5) in Table 5 or Table A.7, depending on whether we use 2008 or 2022 costs predictions.32 We first restrict the planner to place all stations

---

31Our procedure does not guarantee a global optimum, but we verify that it yields the best outcome when each station is individually shifted over a 10 km range from the proposed optimum. Appendix Figure A.5 shows this check in the case of an apolitical planner discussed next.

32Since population density and the share of non-white residents are insignificant, we use the centroid of the confidence set conditional on these two parameters being zero; this implies: $b = [0.00, 0.39, 0.00]$. Figure A.3 in Appendix F displays the topology of the confidence set from column (5) by showing pairwise projections for each combination of the parameters $b_k$ and $\lambda$. 

30
along the rail line corresponding to the actual CHSR design, and explore below the setting in which the planner places the stations along the alternative rail line along the I-5 highway.

Figure 6 shows in red circles the stations that maximize the expected welfare of the apolitical planner, in black diamonds the stations in the proposed CHSR design, and a color scale from blue to red to indicate the welfare changes in different locations. The optimal design of the apolitical planner is quite different from the proposed one. In general, political motives shift stations away from high-density areas of Los Angeles and San Francisco. These locations have already strong preferences in favor of the CHSR; as a result, the elasticity of the favorable vote share with respect to the real income of their residents is low. Hence, in the absence of political motives, several stations that, according to the original proposal, were located in suburban areas of San Francisco (such as San Jose), Los Angeles (Palmdale, Sylmar, Burbank) and San Diego (Escondido) are reallocated towards their corresponding metropolitan areas.

Figure 6: Apolitical Planner, Optimal Station Placement

Notes: The maps shows the change in welfare $\Delta \log \hat{W}(i)$ in each location according to color scale on the right.
Table A.8 in Appendix F displays the cross-sectional impact of the counterfactual CHSR design using the 2008 cost predictions. We find that locations with low voting elasticity experience the largest gains. This implies a redistribution of welfare towards high population density urban areas, which also feature a higher share of non-white residents. Appendix Figure A.6 zooms in on the Los Angeles region, displaying the real income changes (left panel) and the voting elasticity (right panel). The relocation of stations towards more central locations redistributes welfare towards the city center and away from the suburbs, in line with a general redistribution pattern towards high density areas that have low voting elasticity.

Table 6 shows the difference in aggregate real income (defined as the population-weighted average of $\ln \hat{W}(i)$) and votes between the optimal design of the apolitical planner and the proposed CHSR design, under the projections of both the 2008 and the 2022 Business Plans. As expected, aggregate real income increases and the aggregate vote declines when the planner does not care about votes. Compared to the baseline aggregate gains from the proposed CHSR, shown in Appendix Table A.3, the aggregate real income that is foregone due to political preferences is substantial. With 2008 costs, the planner foregoes 0.16 percentage points of aggregate real income to obtain 0.15 additional percentage points in favorable votes (baseline real income gains are 0.16%). Using the 2022 cost projections, the planner foregoes 0.08 percentage points of aggregate real income to obtain 0.08 additional percentage points in favorable votes (baseline real income change is $-0.21\%$).

In sum, a politically-blind planner would have designed a network with twice the expected economic gains (using 2008 costs) or about 40% smaller losses (using 2022 costs).

The optimal station distribution of a utilitarian planner ($\lambda_U(i) = 1$ and $\lambda_V = 0$) does not differ significantly from the apolitical one, except that some stations are shifted from high to low college-share areas, as illustrated for the case of San Diego in Appendix Figure A.7. The main beneficiaries

Notes: The table shows differences in outcomes between the optimal counterfactual design of an apolitical planner with $\lambda_V = 0$ and the baseline CHSR design. Aggregate welfare is the population-weighted average of real income differences with respect to the baseline CHSR. The aggregate welfare gains under the baseline CHSR are shown in the last column of Appendix Table A.3. The rows [min max] show the support of $\ln \hat{W}(i; d^*)$ across locations.

Additional details are provided in Table A.9 in Appendix F, which shows how welfare changes between the optimal plan and one in which each station is individually moved back to its location in the original CHSR proposal. In line with our previous explanation, the largest welfare gains arise from stations that move closer to dense urban areas, also causing the largest vote losses (such as San Francisco, San Jose, Palmdale, Burbank, Sylmar).
from eliminating the planner’s preference for high college-share locations are areas in downtown San Diego, whose population exhibits a mix of high and less educated residents. Compared to the proposed design, the aggregate welfare gains associated with the optimal placement of stations of the utilitarian planner are 0.16% under the projections in the 2008 Business Plan. These gains are very similar to those obtained by the apolitical planner. This result suggests that the key factor behind the lower aggregate welfare gains associated to the proposed CHSR is the weight that the actual planner put on votes.

**Optimal Stations Along the I-5 Highway** The I-5 route differs from the proposed one in that it provides a faster and more direct connection between San Francisco and Los Angeles. By connecting these two cities through a route of 603.57km, as opposed to a length of 1242.02km for the proposed route, adopting the I-5 route would have resulted in lower costs. However, it would have served fewer destinations, by removing the Sacramento, Anaheim, and San Diego segments.

A possible reason why the I-5 route was not chosen is the planner’s positive preference for votes.

![Figure 7: Welfare Change between Optimal I5 and Proposed CHSR Plan](image)

Notes: 2008 Business Plan estimates. The maps shows the change in welfare $\Delta \log \hat{W}(i)$ (I5 minus baseline) in each location according to color scale on the right under the estimated policymakers’ preferences.
To determine whether this is the key factor, we consider an apolitical planner (i.e., set $\lambda V = 0$ and leave the other parameters at the centroid of the confidence set) and solve the location of the 24 stations along this alternative route that maximizes the utility of this apolitical planner. When evaluating the costs of this alternative route, we reduce the projected costs for the original plan in proportion to the length of the alternative route relative to the proposed one.

Figure 7 displays the I-5 route with the preferred station placement of the apolitical planner, and shows the welfare changes relative to the proposed plan. The lower costs of this alternative route result in welfare gains in most locations, including in some areas served by the CHSR in the proposed plan that would loose access if the I-5 route was adopted (e.g., the Central Valley). The main losers from this alternative design are areas South and East of L.A., as well as locations along the San Diego and Sacramento corridors which no longer have access to the line.

Aggregating winners and losers, we find a total loss for the apolitical planner (-0.0804%) compared to the proposed CHSR. Thus, a planner with no preferences for votes would have also chosen the proposed CHSR through the Central Valley over the I5 route. We conclude that the route along the I-5 highway was not discarded due to political preferences.

7 Conclusion

We study the role of policymakers’ and households’ preferences in shaping transportation infrastructure projects. We use the California High-Speed Rail as the basis of our study, leveraging the fact that we observe vote shares in favor of this project across California’s census tracts. The empirical analysis reveals that voters did respond to the expected real-income impacts of the CHSR. So, in this context, economic voting was a significant driver of policy preferences over transport infrastructure.

We posit that the proposed CHSR design represents the optimal choice of a planner, whose preferences we estimate using moment inequalities. Our estimator infers the planner’s preferences by comparing the value of the planner’s objective function under the proposed plan to that under alternative designs. We find that the planer selected a design that increased the total number of favorable votes in the 2008 referendum at the expense of alternative designs that would have resulted in a smaller electoral support but larger aggregate welfare. We thus conclude that attaining popular approval was an important driver of the proposed design of the California High-Speed Rail.

As a result of these preferences for gaining votes, stations were placed further away from the main metropolitan areas than it would have been optimal from an aggregate welfare maximization perspective alone. Our economic model and moment inequality methodology may be generally applied to infer the considerations taken into account by policymakers in charge of the design of large and complex transport networks.

A Full Description of the Economic Model

We model an economy with a set $\mathcal{J}$ of tracts, each tract $i$ with a fixed resident population $N_R(i)$ and connected to other tracts by various transport modes. Residents consume a traded good, floor space, and leisure trips. They choose where to commute to work, where to take leisure trips, how many such trips to make, and what transport mode to use for each travel purpose and origin-destination pair. The discrete choices of destination and travel mode are governed by idiosyncratic shocks to residents’ preferences. Across tracts, residents are heterogeneous in average preferences over transport modes and leisure destination, efficiency units of labor, and ownership of the local floor space.

Traded good firms produce using labor, floor space, and business trips with constant returns to scale. They choose where to send workers to business trips, how many such trips to make, what transport mode to use, and through what route in the transport network. The discrete choices of business travel destination and travel mode are governed by idiosyncratic shocks to firms’ productivity. Across tracts, firms are heterogeneous in terms of average preferences over transport modes and business destination, and productivity. In addition, tracts are heterogeneous in terms of the level of endogenous amenities enjoyed by their residents and the stock of floor space.

All the transport modes operate constant-returns technologies using the tradeable good as input, with ticket prices covering the price of each trip. The CHSR network is constructed with a fixed investment financed from income taxes. The rollout of the CHSR endows the economy with an option of making faster or cheaper trips along some routes within specific modes compared to the status quo.

In the presentation of the model, variables that are indexed by $s$ may change either endogenously or exogenously based on whether the CHSR proposition passes ($s = Y$) or not ($s = N$).

A.1 Preferences

When the CHSR status is $s$, the utility $v_\omega$ of an individual $\omega$ living in tract $i$ who travels to $j_C$ for commuting and to $j_L$ for leisure, by transport modes $m_C$ and $m_L$ respectively, is:

$$v_\omega(i, j_C, j_L, m_C, m_L, s) = \max_{C, H_C, T_L, \beta, \mu, \lambda, \mu_H, \mu_L} \int_{C} B(i, s) \left[ \frac{C - \mu_L - \mu_H \cdot H_C^{\beta}}{d_C(i, j_C, m_C, s)} \left( q_L(i, j_L) B(j_L, s) T_L \right)^{\mu_L} \right] \epsilon_C^{j_C} \epsilon_L^{j_L} \eta_{m_C} \eta_{m_L}. \quad (A.1)$$
subject to the budget constraint:

\[ C + r (i, s) H_C + p_L (i, j_L, m_L, s) T_L = I (i, j_C, m_C, s) \]  \hspace{1cm} (A.2)

Expression A.1 indicates that consumers derive utility from the amenities of their place of residence \( B (i, s) \) and from the consumption of tradeable commodities \( C \), housing \( H_C \), and leisure trips \( T_L \), with Cobb-Douglas shares \( \mu_H \) and \( \mu_L \). The amenity term \( B (i, s) \) may respond endogenously to the local density of economic activity as detailed below. These workers face disutility \( d_C (i, j_C, m_C, s) \) from daily commuting travel. The utility that they derive from leisure trips depends negatively on time travelled \( d_L (i, j_L, m_L, s) \) and positively on the quality of the destination visited, equal to a composite of an exogenous origin-destination component \( q_L (i, j_L) \) (capturing, for example, that residents of some locations may on average be more likely to have relatives in some other specific location) and the destination-specific amenity \( B (j_L,s) \). The last two terms of (A.1), \( \varepsilon^C_w (j_C, m_C) \) and \( \varepsilon^L_w (j_L, m_L) \), are idiosyncratic preference shocks for commuting and leisure travel to each destination by each travel mode.

The utility cost of travel is a power function of travel time \( \tau_k (i, j, m, s) \) and depends on travel mode for both commuting \((k = C)\) and leisure \((k = L)\):

\[ d_k (i, j, m, s) = D_k (i, m) \tau_k (i, j, m, s)^{\rho_k} \quad \text{for} \quad k = C, L, \]  \hspace{1cm} (A.3)

where \( \rho \) is the elasticity of travel disutility to travel time and \( D_k (i, m) \) is a location-specific preference for traveling through transport mode \( m \). This term captures that workers in different tracts may have different tastes for different modes of travel, such as a preference for using cars over public transit.

We turn now to describing the budget constraint A.2. In the expenditure side on the left, the price per unit of tradeable commodities \( C \) is normalized to 1 and the cost per unit of floor space for housing \( H \) is \( r (i, s) \). The monetary cost per round-trip leisure travel from \( i \) to \( j \) using travel mode \( m \) in state \( s \) is \( p_L (i, j, m, s) \). The right-hand side of the budget constraint (A.2) is the disposable income, defined as gross income \( y (i, j_C, s) \) net of taxes \( t (s) \) and annual commuting costs:

\[ I (i, j_C, m_C, s) \equiv (1 - t (s)) y (i, j_C, s) - p_C (i, j_C, m_C, s) T_C. \]  \hspace{1cm} (A.4)

The tax rate \( t (s) \) equals \( t \) if the CHSR is approved \((s = Y)\) and 0 otherwise. Gross income comes from two sources, labor and home ownership:

\[ y (i, j_C, s) \equiv e (i) w (j_C, s) + \eta (i) r (i, s). \]  \hspace{1cm} (A.5)

The returns to labor equal the efficiency units per resident of tract \( i \), \( e (i) \), times the wage per efficiency unit at destination, \( w (j_C, s) \). So, within an origin tract, commuters to different destinations earn different wages based on \( w (j_C, s) \); and, across origin tracts, commuters to the same destination earn different wages based on \( e (i) \). The last term in (A.5) is the return to home-ownership, where \( \eta (i) \) is the locally owned floor space per resident. An increase in land rents \( r (i, s) \) reduces the real income of tract-\( i \) residents through the cost of housing, but it increases it through the returns to land as a function of \( \eta (i) \).
Finally, the round-trip monetary commuting cost of traveling from \( i \) to \( j \) through means \( m \) in state \( s \) is \( p_C(i,j,m,s) \). The annual commuting cost multiplies this per-trip cost by the number of working days through the year, \( T_C \). Unlike for leisure, where the number of trips \( T_L \) is endogenously chosen, the number of commuting trips \( T_C \) is fixed by the number of working days. The resulting demand system is quasi-homothetic, with homothetic demand over \( C \), \( H \), and \( T_L \) after spending \( p_C(i,jC,mC,s)T_C \) annually on commuting.

### A.2 Indirect Utility and Welfare

Maximizing out the solutions for consumption \( C \), housing \( H \) and number of leisure trips \( T_L \), the solution to (A.1) gives indirect utility conditional on the origin, destinations, travel modes, and realizations of the travel purpose:

\[
v_\omega(i,jC,mC,jL,mL,s) = \frac{B(i,s)}{r(i,s)^{\muH(i)}} \left( \frac{I(i,jC,mC,s)}{d_C(i,jC,mC,s)} \varepsilon_C^C(jC,mC) \right) \left( \frac{qL(i,jL)B(jL,s)}{p_L(i,jL,mL,s)d_L(i,jL,mL,s)} \right)^{\muL(i)} \varepsilon_L^L(jL,mL) \tag{A.6}\]

Each resident \( \omega \) makes discrete choices of destination and transport mode for both commuting and leisure to maximizes indirect utility. These choices are represented by the quadruplet \( \{jC,jL,mC,mL\} \). Destinations are chosen from the set of tracts \( J \) while the set of transport modes for travel purpose \( k = L,C \) is \( M_k \). We assume the idiosyncratic preference shocks for commuting and leisure travel \( \varepsilon_C^C(jC,mC) \) and \( \varepsilon_L^L(jL,mL) \) to be IID Type-I extreme value distributed:

\[
\Pr(\varepsilon_k^k(j_k,m_k) < x) = e^{-e^{-\theta_kx}} \text{ for } k = C,L, \tag{A.7}\]

where \( \theta_k \) maps to the (inverse) of the dispersion of shocks across travel modes and destinations for travel purpose \( k = C,L \).

The average yearly real income of tract-\( i \)-residents is defined as the expected value of indirect utility across the realizations of the \( \varepsilon_C^C \) and \( \varepsilon_L^L \) preference shocks, that is:

\[
V(i,s) = \mathbb{E}_\omega \left[ \max_{(jC,jL,mC,mL) \in J^2 \times M_C \times M_L} v_\omega(i,jC,mC,jL,mL,s) \right]. \tag{A.8}\]

Using standard properties of the extreme-value distributions for the shocks \( \varepsilon_C^C \) and \( \varepsilon_L^L \), we can write this expression as:

\[
V(i,s) \propto \frac{B(i,s)}{r(i,s)^{\muH(i)}} \frac{\Omega_C(i,s)}{\Omega_L(i,s)^{\muL(i)}}, \tag{A.9}\]

with a constant of proportionality that is independent from \( i \), and where \( \Omega_C(i,s) \) captures average

\[\text{As an intermediate step, we exploit that the idiosyncratic preference shocks are independent, and so are the travel choices:}\]

\[
V(i,s) = \mathbb{E}_\omega \left[ \max_{jC,mC} \left( \frac{I(i,jC,mC,s)}{d_C(i,jC,mC,s)} \varepsilon_C^C(jC,mC) \right) \right] \frac{B(i,s)}{r(i,s)^{\muH(i)}} \frac{\Omega_C(i,s)}{\Omega_L(i,s)^{\muL(i)}}, \tag{A.10}\]
income net of commuting costs of residents of \( i \),

\[
\Omega_C (i, s) = \left( \sum_{j \in J} \sum_{m \in M_C} \left( \frac{I (i, j, m, s)}{d_C (i, j, m, s)} \right)^{\theta_C} \right)^{\frac{1}{\theta_C}},
\]  

(A.10)

and where \( \Omega_L (i, s) \) is akin to a quality-adjusted price index for leisure trips for residents of \( i \), net of travel costs:

\[
\Omega_L (i, s) \equiv \left( \sum_{j \in J} \sum_{m \in M_C} \left( \frac{p_L (i, j, m, s) d_L (i, j, m, s)}{q_L (i, j) B (j, s)} \right)^{-\mu_L \theta_L} \right)^{-\frac{1}{\mu_L \theta_L}}.
\]  

(A.11)

### A.3 Tradeable Sector Firms

In the tradeable sector, we assume a measure of firms in each tract. Tracts differ in their productivity \( A (j, s) \). Each firm uses floor space \( H_Y \), labor \( N_Y \), and business trips \( T_B \) as inputs. A firm \( \omega \) sending workers on \( T_B \) business trips to destination \( j_B \) using transport mode \( m_B \) produces output according to the Cobb-Douglas production function:

\[
Y_\omega (j, H_Y, N_Y, R_B, j_B, m_B, s) = A (j, s) H_Y^{\mu_Y} N_Y^{1-\mu_Y} - \mu_B \epsilon \omega (j_B, m_B).
\]  

(A.12)

Business trips are productivity-enhancing, capturing for example that they promote new supplier or customer relationships. Specifically, the returns to business trips depend on the productivity of the destination \( A (j_B, s) \), on an exogenous origin-destination productivity match \( q_B (j, j_B) \) (capturing that firms in some locations may on average be more likely to find business partners in some specific locations), and negatively on time traveled (captured by \( d_B (j, j_B, m_B, s) \)). Finally, the return to business trips also depend on an idiosyncratic productivity shock \( \epsilon \omega (j_B, m_B) \) for the destination and travel mode for these business trips. We assume them to be IID Type-I extreme value distributed:

\[
\Pr \left( \epsilon \omega (j_B, m_B) < x \right) = e^{-e^{-\theta_B x}},
\]  

(A.13)

where \( \theta_B \) is the (inverse) of the dispersion of shocks across travel modes and destinations for business travel.

We assume that firms hire labor and floor space before observing the realizations of the idiosyncratic business opportunity shocks. Then, they choose the business trip destination (from the set of locations \( J \)), the transport mode (from the set of available modes \( M_B \)), and the number of trips \( T_B \). Hence, a firm in \( j \) solves the problem:

\[
\Pi = \max_{H_Y, N_Y} \mathbb{E} \left[ \max_{(T_B, j_B, m_B) \in (\mathbb{R}^+ x J x M_B)} Y_\omega (j, H_Y, N_Y, R_B, j_B, m_B, s) - p_B (j, j_B, m_B, s) T_B + w (j, s) N_Y - r (j, s) H_Y \right]
\]  

(A.14)

where \( p_B (j, j_B, m_B, s) \) is the monetary cost per roundtrip business trip. Because conditional on floor space and labor there are decreasing returns to the number of trips, we can solve for the number of trips \( T_B \), plug them back into the term within the expectation, and then integrate over realization of idiosyncratic business shocks using standard properties of the extreme value distribution defined in (A.13).
After these steps, we obtain a closed-form solution for the expected output net of business costs (the term within brackets in (A.14)). Specifically, the firm problem over floor space and labor can be re-written as follows:

\[
\Pi = \max_{H_Y, N_Y} \left( \Omega_B (j, s) H_Y^{\mu_H Y} N_Y^{1-\mu_H Y-\mu_B} \right)^{\frac{1}{1-\mu_B}} - r (j, s) H_Y - w (j, s) N_Y. \tag{A.15}
\]

where \( \Omega_B (j, s) \) is an endogenous TFP term that depends on both the TFP of the location \( A (j, s) \) and the distribution of business travel opportunities,

\[
\Omega_B (j, s) \equiv \kappa_B A (j, s) \left( \sum_{j_B \in J} \sum_{m \in M_B} \left( \frac{q_B (j, j_B) A (j_B, s)}{p_B (j, j_B, m_B, s) d_B (j, j_B, m_B, s)} \right)^{\theta_B m_B} \right)^{\frac{1}{\mu_B}}, \tag{A.16}
\]

where we have denoted \( \kappa_B \equiv \mu_B ^{\mu_B} (1-\mu_B)^{1-\mu_B} \).

### A.4 Travel Choices

The travel decisions of workers and firms imply equations for shares and numbers of trips taken to a given destination. We use these equations to estimate key parameters of the model. Specifically, using standard properties of the extreme-value distributions for the shocks \( \varepsilon^C \) and \( \varepsilon^B \), the solution to (A.8) gives the fraction of residents from \( i \) that commute to \( j \) using transport mode \( m \),

\[
\lambda_C (i, j_C, m_C, s) = \frac{\left( \frac{I (i, j_C, m_C, s)}{d_C (i, j_C, m_C, s)} \right)^{\theta_C}}{\sum_{j \in J} \sum_{m \in M_C} \left( \frac{I (i, j, m, s)}{d_C (i, j, m, s)} \right)^{\theta_C}}, \tag{A.17}
\]
as well as the fraction of residents from \( i \) that travel for leisure to \( j \) through transport mode \( m \):

\[
\lambda_L (i, j_L, m_L, s) = \frac{\left( \frac{q_L (i, j_L) B (j_L, s)}{p_L (i, j_L, m_L, s) d_L (i, j_L, m_L, s)} \right)^{\mu_L \theta_L}}{\sum_{j \in J} \sum_{m \in M_L} \left( \frac{q_L (i, j) B (j, s)}{p_L (i, j, m, s) d_L (i, j, m, s)} \right)^{\mu_L \theta_L}}. \tag{A.18}
\]

Similarly, from the solution to the firm’s problem in A.14 and using standard properties of the extreme value shocks \( \varepsilon^B \), the fraction of firms from \( j \) sending workers on business trips to \( j_B \) takes the same functional form as (A.18):

\[
\lambda_B (i, j_B, m_B, s) = \frac{\left( \frac{q_B (i, j_B) A (j_B, s)}{p_B (i, j_B, m_B, s) d_B (i, j_B, m_B, s)} \right)^{\mu_B \theta_B}}{\sum_{j \in J} \sum_{m \in M_B} \left( \frac{q_B (i, j) A (j, s)}{p_B (i, j, m, s) d_B (i, j, m, s)} \right)^{\mu_B \theta_B}}. \tag{A.19}
\]

The last two expressions measure the shares of travelers (or firms) from location \( i \) making leisure (or business trips) to a destination. In the data, we observe the number of trips to each destination by travel purpose. In the model, the number of leisure trips from \( i \) to \( j_l \) through means \( m_L \) depends both on the share of travelers and on the intensity of travel. From the consumer problem (A.1), leisure trips are a constant share \( \mu_L (i) \) of disposable income among location-\( i \) residents. Adding up this optimal choice across residents of \( i \), we obtain that the total number of leisure trips from \( i \) to \( j_L \) using mode \( m_L \) is:

\[
T_L (i, j_L, m_L, s) = \lambda_L (j, j_L, m_B, s) \mu_L (i) \frac{N_R (i) \bar{I} (i)}{p_L (i, j_L, m_L, s)}, \tag{A.20}
\]
where $I(i)$ is the average disposable income among location $i$’s residents, itself a function of where they commute for work:

$$\bar{I}(i) \equiv \sum_{j \in J} \sum_{m \in M_C} \lambda_C(i, j, m, s) I(i, j, m, s).$$

Similarly, from the solution for $T_B$ from (A.14), the total number of business trips from $i$ to $j_B$ through mode $m_B$ is:

$$T_B(i, j_B, m_B, s) = \lambda_B(i, j_B, m_B, s) \frac{\mu_B}{1 - \mu_B \rho_B(i, j_B, m_B, s)} Y(i, s).$$

Using (A.20) and (A.22) we obtain the gravity equation (12) that we bring to the data.

A.5 Spillovers

Firm productivity and residential amenities may respond endogenously to the level of local activity. We use similar functional forms as Ahlfeldt et al. (2015) and assume that spillovers respond to the density of workers in the location and in the surroundings:

$$A(j, s) = Z_A(j) \left( \sum_{k \in J} e^{-\gamma_A^{\text{spillover}} \tau_{\min}(j, k, s)} \tilde{N}_Y(k, s) H(k) \right)^{\gamma_A^{\text{spillover}}}$$

$$B(i, s) = Z_B(i) \left( \sum_{k \in J} e^{-\gamma_B^{\text{spillover}} \tau_{\min}(j, k, s)} \tilde{N}_Y(k, s) H(k) \right)^{\gamma_B^{\text{spillover}}}$$

where

$$\tilde{N}_Y(j, s) = \sum_{i} \lambda_C(i, j, m) N_R(i)$$

is the number of workers employed in $j$ and $H(j)$ is the available floor space, so that $\tilde{N}_Y(j, s)$ worker density in $j$ and $\tau_{\min}(j, k, s)$ is the fastest travel time across all modes over a given route. In Ahlfeldt et al. (2015), the congestion at residence (denominated $B$ here) depends on how many people live around an area, while the agglomeration at destination (denominated $A$ here) depends on how many people work around an area. Since we assume a fixed number of residents, in our case both spillovers are a function of the endogenous number of workers in the surrounding areas. Similarly, in Ahlfeldt et al. (2015), the surrounding density is discounted by the $\rho$ elasticities times travel time. Since we have multiple travel mode, in our case we use the fastest travel time across all travel modes.

A.6 Route Choice and High-Speed Rail Use

The travel time $\tau_k(i, j, m, s)$ and the roundtrip monetary cost $p_k(i, j, m, s)$ introduced so far for each travel purpose $k = C, L, B$ are the time and the cost corresponding to the actual route chosen in the transport network to travel from origin $i$ to destination $j$ through mode $m$ for purpose $k$ in state $s$. Without the CHSR (i.e. when $s = N$) we use the travel time corresponding to the fastest route between a given origin and destination for a given mode and assign a monetary cost to this
When the CHSR is available (i.e., when $s = Y$), the CHSR is treated as a perfect substitute to traveling via public transit (for commuters) or by air (for business and leisure travelers). That is, the CHSR is used within mode $m$ for each pair $(i, j)$ if the CHSR-based time-cost pair $(\tau, p)$ leads to a higher indirect utility than the pre-CHSR one. Given the indirect utility (A.6), this trade-off is summarized by:

$$\left(\tau_C (\cdot, Y), p_C (\cdot, Y)\right) = \arg \max_{(\tau, p) \in \{(\tau_C (\cdot, N), p_C (\cdot, N)), (\tau_{CHSR (\cdot), p_{CHSR (\cdot)})\}} \frac{(1 - t) y (i, j, Y) - pT_C}{\tau p}. \quad (A.26)$$

Similarly, as implied by the indirect utility (A.6) and by the definition of business productivity (A.16), a leisure ($k = L$) or business ($k = B$) traveler chooses a post-CHSR time and cost pair by solving:

$$\left(\tau_k (\cdot, Y), p_k (\cdot, Y)\right) = \arg \min_{(\tau, p) \in \{(\tau_C (\cdot, N), p_C (\cdot, N)), (\tau_{CHSR (\cdot), p_{CHSR (\cdot)})\}} p\tau p^{\theta} \quad (A.27)$$

for $k = L, B$. When $s = Y$ (i.e., when the CHSR is available), the times and costs $\tau_k (i, j, m, Y)$ and $p_k (i, j, m, Y)$ on a given origin-destination may be different for commuters and for leisure or business travel, because the monetary costs from using the CHSR enter asymmetrically in indirect utility depending on the travel purpose.

### A.7 Equilibrium Conditions

Equilibrium in the labor market of tract $i$ dictates that the demand for efficiency units of labor in a location equals the supply of efficiency units to that location, $N (i, s)$:

$$N_Y (i, s) = \sum_{j \in J} \lambda_C (j, i, s) e (j) N_R (j) \equiv N(i, s) \quad (A.28)$$

where $\lambda_C (j, i, s)$ fraction of commuters from $j$ to $i$ through any mode:

$$\lambda_C (j, i, s) \equiv \sum_{m \in M_C} \lambda_C (j, i, m, s). \quad (A.29)$$

Next, using the solution for consumer demand for floor space from (A.1) and for firm’s demand for floor space and labor from (A.14), the equilibrium in the housing markets is:

$$N_R (i) = \frac{\mu_H (i)}{r (i, s)} T (i) + N_Y (i, s) w (i, s) \frac{\mu_H (i)}{r (i, s)} \frac{N_Y (i, s)}{1 - \mu_H (i) - \mu_B (i)} = H (i), \quad (A.30)$$

where the first term in the left-hand side is the demand for floor space coming from residents of $i$, the second term is demand coming from firms located in $i$, and $H (i)$ is the supply of floor space in $i$. Finally, since tradeable firms operate subject to constant returns, the zero-profit conditions resulting from (A.14) dictates:

$$w (j, s)^{1 - \mu_B - \mu_H} r (j, s)^{\mu_H} = \kappa_{\Omega} \Omega_B (j) \quad (A.31)$$
for some constant $\kappa_\Omega$ that is a function of $\mu_B$ and $\mu_H$. An equilibrium consists of distributions of land prices $r(j,s)$, wages $w(j,s)$, and supplies of labor into tradeables $N_Y(i,s)$, such that:

i) the land market clearing condition (A.30) holds for all tracts;
ii) the labor market clearing condition (A.28) holds for all tracts $i$; and
iii) the zero-profit condition (A.31) holds for all tracts $j$.

Note that the system of equations defined by (A.30)-(A.31) include as unknowns the endogenous productivity term $\Omega(j)$, the agglomeration and amenity spillover functions $A(j,s)$ and $B(i,s)$, and the average income $\mathbf{T}(i)$. Using (A.16), (A.23), (A.24), and (A.21), all these endogenous variables can be expressed as functions of the endogenous variables $\{r(j,s), w(j,s), N_Y(i,s)\}$ which define the equilibrium.

A.8 System for Counterfactual Analysis

In this section we derive the system that we implement when running counterfactuals. For this, we now move to express the equilibrium value of every endogenous outcome in a scenario where $s = Y$ relative to its value in an equilibrium where $s = N$. We let

$$X(\cdot) = \frac{X(\cdot, Y)}{X(\cdot, N)}$$

be the ratio of variable $X$ between its equilibrium value when $s = Y$ (so that the CHSR will be built with some probability) and when $s = N$ (the CHSR is not built).

**CHSR Shock** Starting from an initial equilibrium, the previous system of equilibrium conditions is impacted by potentially different travel times and monetary travel costs. Specifically, the shock to the system is given by time changes,

$$\hat{\tau}_k(i,j,m)$$

and by monetary travel cost changes,

$$\hat{p}_k(i,j,m)$$

for each travel purpose $k = C, L, B$ (commuting, leisure, or business travel). The pre- and post-CHSR levels of these variables are defined in (A.26) and (A.27). On route-mode combinations $(i,j,m)$ where travelers do not choose CHSR, these shocks are $\hat{\tau}_k(i,j,m) = \hat{p}_k(i,j,m) = 1$. On route-mode combinations where CHSR is preferred to the pre-existing mode then either $\hat{\tau}_k(i,j,m) < 1, \hat{p}_k(i,j,m) < 1$, or both. To construct these shocks, we use the pre- and post-CHSR travel times and costs following the discussion in Section A.6. When $s = Y$, then disposable income also changes with the tax rate in a common away across locations:

$$\tilde{1} - \tilde{t} = 1 - t.$$

**Equilibrium System in Relative Changes** The equilibrium response to $\{\hat{\tau}(i,j,m), \hat{p}_k(i,j,m), 1 - t\}$ consists in changes in land rents $\hat{r}(i)$, wages $\hat{w}(i)$, and labor supplies $\hat{N}_Y(i)$ such that:
\begin{align*}
\hat{\lambda}_C (j, i, j, m) &= \frac{\hat{\lambda}_C (j, i, m, N)}{C(j, i, j, m, N)} \theta_C \\
\hat{\lambda}_C (j, i, j, m) &= \sum_{j \in J} \sum_{m \in M_C} \lambda_C (j, i, m, N) \left( \frac{\hat{\lambda}_C (j, i, m, N)}{C(j, i, m, N)} \theta_C \right) \\
\hat{\lambda}_C (j, i, m) &= \sum_{j \in J} \sum_{m \in M_C} \lambda_C (j, i, m, N) \left( \frac{\lambda_C (j, i, m, N)}{\lambda_C (j, i, N)} \right) \hat{\lambda}_C (j, i, m) .
\end{align*}

\( i \) The land market clears, i.e. \((A.30)\) holds in the counterfactual equilibrium, which implies:

\[
\hat{\lambda}_C (i, j, m, N) = \frac{\hat{\lambda}_C (i, j, m, N) \hat{\lambda}_C (i, j, m)}{\hat{\lambda}_C (i, j, m, N) \hat{\lambda}_C (i, j, m)} .
\]
A.9 Welfare Changes

From (7) to (9) we obtain the following expressions for the welfare change:

\[
\hat{V}(i) = \left( \frac{\hat{B}(i)}{\hat{r}(i)^{\mu_H}} \right) \hat{\Omega}_C(i) \hat{\Omega}_L(i).
\]  

(A.42)

The commuting component \(\hat{\Omega}_C(i)\) changes according to (8), with \(\hat{I}(i,j,m)\) in that expression given by (A.34). The leisure changes according to

\[
\hat{\Omega}_L(i) \equiv \left( \sum_{j \in J} \sum_{m \in M_L} \lambda_L(i,j,m) \left( \frac{\hat{B}(j)}{\hat{p}_L(i,j,m) \hat{r}(i,j,m)^{\rho}} \right)^{\mu_L \theta_L} \right)^{\frac{1}{\theta_L}}.
\]

(A.43)

In these expressions, endogenous amenities component \(\hat{B}(i)\) satisfies a similar equation to \(\hat{A}(j)\) in (A.40):

\[
\hat{B}(j) = \left( \sum_{k \in J} \sum_{k' \in J} e^{-\rho^{\text{spillover}_{\text{min}}}B(j,k')} \frac{\hat{N}_Y(k,N)}{H(k)} \frac{\hat{N}_Y(k',N)}{H(k')} e^{-\rho^{\text{spillover}}B(j,k')} \hat{N}_Y(k) \right)^{\rho^{\text{spillover}}}. \]

(A.44)

Conditions (7) and (9) in the text follow from (A.42) and (A.43) when we set \(\hat{B}(i) = \hat{r}(i) = 1\).

B Data Sources

Geographic Units The analysis is conducted at the tract level. Our sample comprises 7866 out of 8057 census tracts in California’s mainland that are populated and have positive employment and no missing data (U.S. Census (2008b) and U.S. Census Bureau (2010a)). These tracts account for 98.5% of the state’s population and 97.6% of all tracts.

Voting We obtain data on the number of favorable and negative votes by precinct for Proposition 1A and for other ballots in 2006 and 2008 from the UC Berkeley’s Statewide Database (University of California, Berkeley (2008)). We also use their crosswalk to construct a tract-level dataset of votes.

Commuting Data on commuting flows are taken from the American Community Survey (ACS) (U.S. Census Bureau, 2010b). The American Community Survey reports tract-to-tract data on commuting by transport mode as a part of the Census Transportation Planning Products.\(^2\) To measure commuting flows, respondents answer the question: “At what location did this person work LAST WEEK?” We construct the flows excluding work-from-home workers, corresponding to less than 5% of statewide workers in this period. In addition, to measure the mode of travel, respondents are asked: “How did this person usually get to work LAST WEEK?”. We classify car, truck, or van as the “car” mode. We classify the bus, subway, commuter rail, light rail, or ferry as

\(^2\)The LEHD also reports commuting flows by origin and destination based on administrative data linking employees home locations with their employer’s location. As we do not observe the frequency at which these trips are taken, these origin-destination flows may not reflect regular commuting.
the “public transit” mode. Finally, we classify the remainder, which includes biking and walking as the “walking or biking” mode.

**Leisure and Business trips** Leisure and business trips are compiled from the California Household Travel Survey (CAHTS) conducted between 2010 and 2012. The CAHTS records trips longer than 50 miles taken over a 8-week survey period. 18,008 households and 68,193 trips appear in the dataset. The data include information on the origin, destination, and residence census tract of each trip, the number of people on each trip, the travel mode, and the purpose of the trip. We classify each trip into a leisure trip if the purpose includes entertainment, vacation, shopping or visiting friends and family. The top leisure destinations are Disneyland, Yosemite, Mission Beach (San Diego), Downtown San Francisco, and Downtown San Diego. We classify each trip into a business trip of the purpose includes business meetings, conventions, or seminars. The top business destinations are the State Capitol in Downtown Sacramento, Downtown Los Angeles, Downtown San Francisco, and Downtown San Diego. Taken together, leisure and business trips account for 84% of all trips in the survey. The remaining trips include combined business and pleasure trips, medical trips, school-related activities, and trips for which the purpose is not stated.

**Wages** We use data on wages by workplace Census tract and residence Census tract from the 2008 and 2019 samples of the Longitudinal Employer-Household Dynamics (LEHD) Origin-Destination Employment Statistics published by the U.S. Census (U.S. Census (2008a)). The LEHD reports the number of workers in each workplace-residence Census tract pair who have monthly earnings below $1,250, between $1,250 and $3,333, and above $3,333. To construct an average wage along each route, we first measure average earnings within each of these three bins within California using the individual level American Community Survey samples in 2008 and 2019. We use these bins and our estimates of average earnings within each bin to compute average earnings among workers within each workplace-residence tract pair.3

**Population and Demographics** We define the number of working-age residents \(N_R(i)\) entering in the model quantifications using the distribution of commuters originating in each census tract from each ACS with a re-scaling to match the working-age population of California according to the BLS.

We measure share of non-white residents, occupational composition, the share of residents with a college degree, and demographic covariates by census tract from the 2006-2010 and 2015-2019 American Community Survey five-year estimates.

**Construction of Additional Variables** Using the previous sources we construct additional variables needed for the implementation of the model. We construct disposable income \(y(i,jc,N)\) in (A.5) using its definition as the sum of labor income and locally owned land rents. We construct

---

3We use the 2012-2016 sample because the 2016-2020 sample is not yet available, and also encompasses the start of the COVID-19 pandemic, which saw large changes in commuting patterns.
the land rent component of income as \( \eta (i) r (i, N) \equiv \frac{\eta_R (i) r (i, N) H_C (i, N)}{N_R (i)} \), where \( \eta_R (i) \) is the share of homes that is owner-occupied from ACS and \( r (i) H_C (i, N) \) are residential home values from ACS transformed to annualized rent-equivalent values. We measure the share of land used for residential purposes, \( H_C (i, N) / H (i) \) entering in (A.32), using Zillow’s ZTRAX data. We construct the disposable income \( I (i, j_C, m_C, N) \) defined in (A.4) using \( y (i, j_C, N) \), the round-trip commuting costs described in the next section, and \( T_C = 250 \) commuting trips throughout the year.

**Additional Parameter Calibration** We calibrate the remaining parameters using estimates in the literature. We assume that the share of firm expenditure on floor space is \( \mu_{H,Y} = 0.20 \), in line with Valentinyi and Herrendorf (2008). We use estimates from Ahlfeldt et al. (2015) to calibrate the productivity and amenity spillovers from equations A.23 and A.24. Specifically, using their preferred estimate from Table V, column 3, we assume: \( \gamma_{spillover}^A = 0.071 \), \( \gamma_{spillover}^B = 0.155 \) and \( \rho_{spillover}^A = 0.361 \), \( \rho_{spillover}^B = 0.759 \).

**C Transport Network Details**

**Transport Network** We construct a transport network to calibrate times and costs from each census tract origin to each census tract destination, for each possible transport mode: car, public transit (combining bus and rail stations), air travel, biking, and CHSR. The centroid is defined as the geographic centroid of the most populous Census block within each tract. We construct the road network based on the 2010 primary and secondary road shapefile for California obtained from the U.S. Census, which we transform into a graph. We connect the tract centroids to the road network by creating links from the centroids to closest node on the road network. The resulting road network has 72790 edges and 71957 nodes, of which 7866 correspond to the centroids of our analysis. To this network we add a rail network with 192 train stations obtained from California’s Department of Transportation for 2013, which is the closest available year to 2008.\(^4\) We construct the air network including the 10 largest airports in California: LAX, SFO, SAN, OAK, SJC, SNA, SMF, ONT, BUR, LGB.

We include the 24 unique air routes operating among these airports according to the Bureau of Transportation 2008 airline ticket dataset (Bureau of Transportation Statistics (2008a)).\(^5\) Finally, for the CHSR, we obtain a shapefile of the planned route and stations at the time of the vote in November of 2008 from the University of California at Davis.\(^6\) The 2008 CHSR map includes 24 stations and two potential stations (Irvine and Tulare). We exclude these two planned stations, as a total of 24 stations is consistent with the description of the network in the original CHSR bill passed by the California legislature before the 2008 vote. The resulting transport networks includes the road network expanded with tract centroids, rail stations, airports, and CHSR stations. Similar

\(^5\)Available at: [https://www.transtats.bts.gov/DatabaseInfo.asp?QO_VQ= EFI&Yv0x=D.](https://www.transtats.bts.gov/DatabaseInfo.asp?QO_VQ= EFI&Yv0x=D.)

\(^6\)Available at: [https://databasin.org/datasets/7a9f1867f2e24a1e97ab10419a73b25a/].
to centroids, we create artificial edges that connect the rail stations, airports, and CHSR stations to their closest node on the original road network.

**Travel Times** We calibrate speeds by private car and public bus by assigning a travel time to each edge of the road network to match travel times by car only and by public transit only from Google Maps on a random sample of 10,000 origin and destination tracts. We assign travel times by multiplying the arc-length kilometer distance of each edge by its average speed, using one of 5 speed categories for each edge depending on its features (primary urban, primary rural, secondary urban, secondary rural, and artificial centroid-node link). We add a time constant to every trip that is independent from distance and captures waiting times. We closely match the Google times for car trips, whereas we tend to somewhat under-estimate travel times for long trips via public bus.

The fastest route via car is computed on the calibrated road network (all fastest routes are computed using the fast marching method). The fastest route via public transit is defined as the fastest between traveling entirely via public bus or via a combination of car and rail for each origin-destination pair. The fastest route via rail assumes that travelers use the train stations nearest to the origin and destination tracts. To construct rail times we use station-to-station rail times available in the websites of rail systems in California (ACE Rail, Amtrak, BART, CalTrain, Coaster, and Metrolink), centroid-to-rail times computed via car, and wait time of 17 minutes at the origin rail station.

Fastest routes on bike on the road network are calculated assuming an average speed of 20 km per hour in urban environments.

The fastest travel time by air is computed assuming road speeds to and from airports, allowing travelers to use any airport regardless of distance to origin and destination tract, using flight times from Google Maps and assuming a wait time of 90 minutes at the origin airport.

Paths and times via CHSR are defined similarly to via rail, with travelers using the stations closest (by car) to the origin and destination tracts. We use planned speeds between contiguous station of the CHSR network from the 2008 Speed Rail Authority’s Business Plan (California High Speed Rail Authority, 2008). Specifically, from the 2008 business plan we assign a speed of either 125, 175, or 220 miles per hour. The resulting pairwise travel times between all stations closely match those reported between major stations. In Section 6.3, when optimizing over stations along the alternative I5 design, we set the speed on each point of the I5 route equal to the speed on its closest point along the original CHSR design.

**Travel Costs** For car, the cost of travel from each origin to each destination on a given route is computed based the per-mile cost of fuel assuming a cost of $3.50 per gallon and fuel efficiency

---

7We exclude origin-destination pairs where driving times to the rail station are greater than 2 hours or where the distance between stations is greater than between the original tracts.

of 21 miles per gallon\textsuperscript{9}. The cost of traveling via bus equals the average one-way adult bus ticket price in the county where the origin census tract is located, according to the American Public Transportation Association (\textit{American Public Transit Association (2010)}), and complemented with data from each county’s website when necessary (average bus fare across all counties equals $2.15). A fixed and variable per-mile cost of traveling via rail is estimated for the Amtrak Capital Corridor in Northern California and applied to the entire rail network. This estimation yields a rail fare with a fixed cost of $2.9 and an extra cost of $0.20 per mile. The cost of air travel on every route is set to the average one-way ticket cost of $151 across routes according to the Bureau of Transportation Statistics.\textsuperscript{10} To calculate the ticket price of the CHSR, we use as basis either the $55 ticket price from LA to San Francisco from the 2008 Business Plan (California High Speed Rail Authority, 2008) or the update of this number to $110 in the 2022 plan (California High Speed Rail Authority, 2022). We project these costs to the full HSR network using the same ratio of variable to fixed costs as a function of distance estimated for the Amtrak Capitol Corridor.

\section*{D Implementation of the Gravity Equations}

\subsection*{D.1 Commuting}

We discuss here in detail how we estimate the parameters of the gravity equation for commuting in 11. First, we allow for three possible travel modes: \( \mathcal{M}_C = \{ \text{walking or biking, car, public transport} \} \). Second, we assume the labor income term entering \( I(i,j,m) \) is the product of an origin-specific component \( e(i) \), which accounts for the possibility that workers that reside in different locations have different human capital, and a destination-specific component \( w(j) \), which accounts for productivity differences across workplaces. We estimate these origin- and destination-specific components using the following estimating equation: \( w_{\text{data}}(i,j) = \exp(\tilde{e}(i) + \tilde{w}(j)) + \varepsilon(i,j) \), where \( w_{\text{data}}(i,j) \) denotes the observed average wage of workers who reside in \( i \) and work in \( j \), \( \tilde{e}(i) \equiv \ln(e(i)) \), \( \tilde{w}(j) \equiv \ln w(j) \), and \( \varepsilon(i,j) \) accounts for all other factors affecting observed average wages that cannot be accounted for by an origin-specific and a destination-specific fixed effect. We assume that \( \varepsilon(i,j) \) does not impact workers’ commuting decisions and is mean-independent of the origin- and destination-specific components; e.g., it captures measurement error in wages as well as wage shocks unexpected to workers when making their commuting decisions. We take this approach because we do not observe \( w_{\text{data}}(i,j) \) for every \((i,j)\) pair.

Third, we consider as feasible commuting choices any pair of origin and destination census tracts and transport mode such that both census tracts are in CA and the travel time is either less than 4 hours (when using either car or public transport) or less than 2 hours (when biking or walking). As a result, we use about 33 million origin-destination pairs between which it is feasible to commute by car, 21 million pairs for public transit, and 5 million pairs for bike or walking. For all of the 7,866 potential origin locations considered in our analysis, there is at least one destination that may

\textsuperscript{10}Available at https://www.transtats.bts.gov/DATABASEInfo.asp?QO_VQ=EFIkYv0x=D .
be reached by car and at least one destination may reached by public transport. Finally, because our information on commuting comes from a finite sample of residents, we allow for the possibility that the observed commuting shares \( \lambda_{C}^{obs} (i, j, m) \) differ from the true ones, \( \lambda_{C} (i, j, m) \), by a term \( \text{error}_{C} (i, j, m) \) that captures sampling error: \( \lambda_{C}^{obs} (i, j, m) = \lambda_{C} (i, j, m) + \text{error}_{C} (i, j, m) \).

We perform the estimation in two steps. First, to estimate \( \theta_{C} \) and \( \rho_{C} \), we use variation in the choice of destination conditional on origin and transport mode. We use the two moment conditions

\[
E \left[ \left( \frac{\lambda_{C}^{obs} (i, j, m)}{\sum_{j'} \lambda_{C}^{obs} (i, j', m)} - \frac{\lambda_{C} (i, j, m)}{\sum_{j'} \lambda_{C} (i, j', m)} \right) X (i, j, m) \right] = 0, \tag{A.45}
\]

where \( X(i, j, m) = (\ln (I (i, j, m)), \ln \tau (i, j, m))' \). We build sample analogues of these moment conditions by averaging across origins \( i \), destinations \( j \), and modes of transport \( m \).

Second, to estimate the preferences \( D_{C} (i, m) \) that residents of a census tract \( i \) have for a particular transport mode \( m \), we model the origin- and mode-specific term \( D_{C} (i, m) \) as a function of observed origin-specific covariates \( X_{C} (i) \) with unknown mode-specific coefficients \( \Psi_{C} (m) \):

\[
D_{C} (i, m)^{-\theta_{C}} \equiv \exp (\Psi_{C} (m) X_{C} (i)).
\]

The vector \( X_{C} (i) \) includes a constant, the share of residents who own a car, the share of residents who are under 30, the share of college-educated residents, the share of nonwhite residents, the log median income, and the log population density. To estimate these parameters, we use variation across origins in the share of commuters that use each transport mode \( m \). Specifically, we use the mode \( m \)-specific moment conditions

\[
E \left[ \left( \sum_{j} \lambda_{C}^{obs} (i, j, m) - \sum_{j} \lambda_{C} (i, j, m) \right) X_{C} (i) \right] = 0. \tag{A.46}
\]

We build a sample analogue of these mode-specific moment conditions by taking an average across all census tracts \( i \).

### D.2 Business and Leisure

We describe the details our procedure to estimate the gravity equation for long-distance leisure and business trips in \( (12) \). The size of the sample containing information on leisure and business trips is much smaller than that containing information on commuting trips and, in particular, contains no information for the residents of certain census tracts, making it impossible to estimate as free parameters the origin-destination and origin-model unobserved effects \( Z_{k} (i, j) \) and \( D_{k} (i, m) \).

To sidestep this data limitation, we write \( Z_{k} (i, j) \) and \( D_{k} (i, m) \) as a function of observable characteristics. Specifically, we let:
the closest beach, a dummy variable for whether \( j \) is in a national park, the share of workers in \( j \) employed in the hospitality sector, and the log total population. The vector \( X_B(j) \) includes the share of workers in management roles in the destination tract and its log total population.

We measure the share of business and leisure trips \( \hat{\lambda}_k(i, j, m) \), travel time \( \tau(i, j, m) \), and travel costs \( p_k(i, j, m) \) as indicated in Section 4.1. Given the limited size of our sample on business and leisure trips, we account for sampling error in our measure of \( \hat{\lambda}_k(i, j, m) \), which we denote as \( \hat{\lambda}_{k,\text{obs}}(i, j, m) \).

The separate identification of \( \theta_k \) and \( \rho \) arises from the response of \( \hat{\lambda}_k(i, j, m) \) to the travel time variable \( \tau(i, j, m) \) and the monetary cost term \( p_k(i, j, m) \). While we follow standard procedures to measure travel times and, thus, are reasonably confident of its accuracy, our measure of the monetary cost of traveling between any two census tracts likely suffers from substantial measurement error. Consequently, we treat the term \( p_k(i, j, m) \) merely as a control and its associated coefficient as a nuisance parameter, and assume that \( \rho \) equals the corresponding parameter entering the commuting equation.

We estimate the remaining parameters following a two-step estimation approach similar to that described in Section D.1. In the first step, we identify \( \theta_k \) and \( \beta_k \) through the following moment condition:

\[
\mathbb{E} \left[ (\lambda_{k,\text{obs}}^{\text{obs}}(i, j | m) - \lambda_k(i, j | m)) X_k(i, j, m) \right] = 0, \tag{A.48}
\]

for \( k = L, B \), where \( X_k(i, j, m) = (X_k(j), \ln \tau(i, j, m), \ln p_k(i, j, m))' \), and \( \lambda_{k,\text{obs}}^{\text{obs}}(i, j | m) \) and \( \lambda_k(i, j | m) \) denote the observed and model-implied shares of trips of type \( k \) from location \( i \) to \( j \) conditional on the transport mode \( m \).

As discussed in Section 4.1, we only observe data for leisure and business trips whose origin and destination tracts are at least 50 miles away; we account for this data selection and build sample analogues of the moment conditions in (A.48) by taking an average across all pairs of origin \( i \) and destination \( j \) that are at least 50 miles apart. Consequently, for each origin tract \( i \), the denominator of \( \lambda_k(i, j | m) \) sums only over this restricted choice set. In the case of trips performed by airplane, we further exclude from the choice set those pairs of origin and destination tracts for which the travel time by airplane is larger than by car. The sample analogue of the moments in (A.48) averages over approximately 24 million pairs of origin and destination tracts among which it is feasible to travel by airplane, and over approximately 52 million pairs of tracts that may be reached by car or public transport.

In a second step, after normalizing the model-specific shifter \( \gamma_k(m) \) to equal zero for \( m = \) airplane, we identify \( \gamma_k(m) \) for \( m = \) private vehicle and \( m = \) public transport using the following two \( m \)-specific moment conditions

\[
\mathbb{E} \left[ \sum_j \hat{\lambda}_{k,\text{obs}}^{\text{obs}}(i, j, m) - \sum_j \hat{\lambda}_k(i, j, m) \right] = 0. \tag{A.49}
\]

We build a sample analogue of these mode-specific moment conditions by taking an average across all origins \( i \).

</tr>
<tr>
<td>Business</td>
<td>-0.09%</td>
<td>-0.08%</td>
</tr>
<tr>
<td>Total</td>
<td>0.16%</td>
<td>-0.21%</td>
</tr>
</tbody>
</table>

Note: This table splits the aggregate welfare change in (6) into the commuting component $\hat{\Omega}_C (i)$ in (8) and the leisure component $\hat{\Omega}_L (i)$ in (9). The gains coming from commuters are computed as coming from their time and cost savings from HSR, holding income constant, plus spillovers in amenities for residents. The gains coming from business travelers are computed as the welfare gains coming from endogenous wage changes, due both to time and cost saving in business traveling from the CHSR and productivity spillovers.

**Note**: * denotes 1% significance level. Robust standard errors in parenthesis. All specifications control for county fixed effects. Columns (1) and (2) present baseline estimates. Columns (3) and (4) present results where each census tract is weighted by the number of votes in the HSR referendum. Columns (5) and (6) present results where each census tract is weighted by the participation rate in the HSR referendum. Columns (7) and (8) present results where we exclude census tracts that are less than 5 km away from the railway line.
Appendix to Section 6 (Planner Preferences)

This section contains additional details on the implementation of the planner’s preference estimation and optimal station location problem.

F.1 Planner’s Preferences Estimation

Design of the perturbations

As indicated in subsection 6.2, our estimation relies on a moment inequality estimator based on a set of perturbations $n \in \mathcal{N}$ of the CHSR design that yield inequalities of the form

$$
\sum_{i=1}^{j} \left[ b_0 + \sum_{k=1}^{K} b_k Z_k (i) + \lambda V \nabla v (i) \right] N_R (i) \Delta \ln \hat{W} (i, d^n) - \epsilon (d^n) \leq 0,
$$

(A.50)

where $\nabla v (i) \equiv \theta V v (i) (1 - v (i))$ is the semi-elasticity of votes to real income. We generate these perturbations with the aim of identifying upper and lower bounds on the parameters $b$ and $\lambda V$.

For each covariate $Z \in \mathcal{Z} = \{Z_1, \ldots, Z_K, \nabla v\}$, we construct a set of potential locations $L (Z)$ corresponding to peaks and troughs of $Z$ along the proposed CHSR lines. We order these locations as a function of their distance to San Francisco along the CHSR outline. To illustrate this procedure, Figure A.2 displays the variation in population density along the proposed CHSR outline highlighting its peaks and troughs as potential station locations (green) in comparison to the proposed ones (red).

For each covariate $Z$, we then define a set of perturbations $\mathcal{N} (Z)$ by moving each station $s = 1 \ldots 24$ individually by a certain number of steps $k = -N_{steps} \ldots -1$ (towards San Francisco) and $k = 1 \ldots N_{steps}$ (towards San Diego) among the set of potential locations. In our baseline specification, we choose $N_{steps} = 2$, which, for a number of 24 stations, generates $24 \times 4 = 96$ perturbations per covariate.

Our final set of perturbations $\mathcal{N} = \cup_{Z \in \mathcal{Z}} \mathcal{N} (Z)$ is the union of these covariate-specific perturbations. In our largest specification (using as covariates population density, the share of college-educated residents, the share of non-white residents and votes) we obtain $4 \times 96 = 384$ perturbations to identify 5 parameters ($b_0, ..., b_K$ and $\lambda V$).

Moment Conditions

To lighten notation, we rewrite the welfare inequality (A.50) for perturbation $n$ (i.e, design $d^n$) as

$$
\Delta W (d^n; \gamma) \equiv \sum_{k=1}^{K+2} \gamma_k X_k (n) - \epsilon (d^n) \leq 0,
$$
where \( \gamma = (b_0, b_1, \ldots, b_K, \lambda_U) \) is the vector of parameters we want to estimate and

\[
X(n) \equiv \begin{pmatrix}
\sum_i N_R(i) \Delta \ln \hat{W}(i, d^n) \\
\sum_i N_R(i) \Delta \ln \hat{W}(i, d^n) Z_1^T(i) \\
\vdots \\
\sum_i N_R(i) \Delta \ln \hat{W}(i, d^n) Z_K^T(i) \\
\sum_i N_R(i) \Delta \ln \hat{W}(i, d^n) \nabla v(i)
\end{pmatrix}.
\]

To obtain upper and lower bounds on each parameter \( \gamma_k \), we create a set of moments indexed by \( e = 1, \ldots, E \) with \( E = 2 \times (K + 2) \). Each moment is associated to a particular sign of the component \( X_k \) evaluated in 2008 at the time when the CHSR was designed. More precisely, for \( e = 1, \ldots, E \), we define the moment

\[
\hat{m}_e(\gamma) = \frac{\sum_{n \in N_e} \Delta W(d^n; \gamma)}{|N_e|}
\]

and associated standard deviation

\[
\hat{\sigma}_e(\gamma) = \left[ \frac{\sum_{n \in N_e} (\Delta W(d^n; \gamma) - \hat{m}_e(\gamma))^2}{|N_e|} \right]^{\frac{1}{2}},
\]

where \( N_e = \{ n \in \mathcal{N} \mid X_e^{2008}(n) \geq 0 \} \) for \( e = 1, \ldots, K + 2 \) and \( N_e = \{ n \in \mathcal{N} \mid X_e^{2008}(n) \leq 0 \} \) for \( e = K + 3, \ldots, E \). Since the subsets \( N_e \subset \mathcal{N} \) are created using information from 2008, we can use the moment condition that \( E[\epsilon(d^n) | I^{2008}] = 0 \). Following the Modified Method of Moments from Andrews and Soares (2010), we construct the statistics

\[
\hat{Q}(\gamma) = \sum_e ^E \left( \max \left( \sqrt{|N|} \frac{\hat{m}_e(\gamma)}{\hat{\sigma}_e(\gamma)}, 0 \right) \right)^2.
\]

We construct a 95% confidence set over parameter \( \gamma \) as

\[
\Gamma = \left\{ \gamma \mid \hat{Q}(\gamma) \leq cv_{95}(\gamma) \right\},
\]

where the critical value \( cv_{95}(\gamma) \) is computed by bootstrap.

**Normalization** The estimation procedure runs into the problem that the planner weights \( \gamma \) are not uniquely determined since for any positive real number \( z > 0 \), \( z \times \gamma \) give the exact same planner preferences. We use two different types of normalizations:

- To guarantee having a bounded confidence set, we use a spherical normalization during the estimation stage, requiring that \( \sum_k (\gamma_k^{\text{sphere}})^2 = 1 \).

- When reporting the result and to make the parameters more directly interpretable, we normalize \( \gamma \) so that the population-weighted average of \( \lambda_U(i) \) is 1 across locations. Specifically, the means that for any \( \gamma^{\text{sphere}} \), we define

\[
\gamma_k^{\text{norm}} = \frac{\gamma_k^{\text{sphere}}}{z(\gamma^{\text{sphere}})}
\]
where

\[ z(\gamma^{sphere}) = \sum_i N_R(i) \left( \gamma_0 + \sum_{k=1}^K \gamma_k^{sphere} Z_k(i) \right). \]

Since the covariates \( Z_k \) are normalized to have mean 0 and standard deviation 1, \( \gamma_k^{norm} \) can be interpreted as is the relative impact on the per-capita Pareto weight of having covariate \( Z_k \) one standard deviation above its mean.

F.2 Planner Optimization

Procedure The optimal station location problem is highly non-convex optimization due to the presence of a sigmoidal functional form of the voting block (neither concave nor convex) and competing complementarities (convex) and substitutabilities (concave) arising in the placement of stations. The optimization problem requires the use of non-convex techniques. The optimization is done in three sequential steps.

First, we use the information in the precomputed perturbation set \( \mathcal{N} \) used for estimation. For each station \( s \), we identify the perturbation \( n \in \mathcal{N} \) with the highest welfare among those that shifted the location of station \( s \), and evaluate a new CHSR design in which station \( s \) is set to that best location. If total welfare increases, we accept this location; if not, we keep the initial location and move on to the next station.

Second, we use a simulated annealing method. A randomly selected station is shifted among the potential locations that were considered when constructing the perturbations. The new location is accepted with a probability that depends on the welfare obtained (1 if welfare increases, and a positive probability even if welfare decreases).

Third, we implement a continuous optimizer. This final step attempts to refine the local optimum obtained by the previous two steps by using a continuous optimizer (specifically, we use simplex or interior-point algorithms). We parametrize the CHSR outline with a cubic spline over its coordinates, allowing us to evaluate welfare over a continuous set of station locations.

These efforts to globally explore the candidate set of station locations do not guarantee identification of the global optimum. Nonetheless, we verify that our final result is a good candidate by checking that it yields the highest possible welfare when each station is moved individually within a range of 10 km from the proposed optimum along the CHSR outline, as shown in Figure A.5 for the case of the apolitical planner using 2008 cost predictions.

Dealing with Expectations Errors The planner’s objective function is defined as the expectation of future welfare, evaluated using information available in year 2008. We cannot compute the expectation term in practice. To deal with this issue, we adopt the same strategy that we used in the estimation: for each potential design \( d \), we evaluate the planner’s objective using time \( T \) data (when the CHSR was projected to be in service) and introduce a forecast error term \( \epsilon(d; \gamma) \)
for each given set of planner weights $\gamma = (b, \lambda)$, defined as

$$
\epsilon(d; \gamma) = \sum_i \lambda U(i; b) N_R(i) \Delta \ln \hat{W}(i, d) + \lambda V \sum_i N_R(i) v(i; d)
$$

$$
- \mathbb{E} \left[ \sum_i \lambda U(i; b) N_R(i) \Delta \ln \hat{W}(i, d) + \lambda V \sum_i N_R(i) v(i; d) \mid T^{2008} \right].
$$

When computing optimal station locations for a counterfactual set of planner weight $\gamma = (b, \lambda_V)$, $\epsilon(d; \gamma)$ is unknown. When optimizing, we assume that the uncertainty driving the forecast error is independent of the planner’s preferences and set $\epsilon(d; \gamma) \equiv \epsilon(d; \hat{\gamma})$ where $\hat{\gamma}$ is the estimated planner’s weights. To evaluate $\epsilon(d; \hat{\gamma})$, we use the property that design $d$ is not optimal under the estimated preferences $\hat{\gamma}$, i.e., that

$$
\sum_i \lambda U(i; \hat{b}) N_R(i) \Delta \ln \hat{W}(i, d) + \hat{\lambda} V \sum_i N_R(i) v(i; d) - \epsilon(d; \hat{\gamma}) \leq 0.
$$

To avoid penalizing alternative CHSR designs, we adopt the lowest possible value for $\epsilon(d; \hat{\gamma})$ and set it to

$$
\epsilon(d; \hat{\gamma}) \equiv \max \left( 0, \sum_i \lambda U(i; \hat{b}) N_R(i) \Delta \ln \hat{W}(i, d) + \hat{\lambda} V \sum_i N_R(i) v(i; d) \right).
$$

**F.3 Additional Tables and Figures for the Planning Problem**

Figure A.2: Potential Station Locations based on Population Density

Notes: Smoothed population density $\hat{n}(i) = \sum_{i'} n(i') e^{-\rho \text{dist}(i, i')}$ where $\rho = 100$ and $\text{dist}(i, i')$ is the arc-degree distance between Census tracts $i$ and $i'$. The x-axis is an indicator of the location between San Francisco ($x = 0$) and San Diego ($x = 1$) as a fraction of the entire CHSR length, with Los Angeles corresponding to $x \approx 0.7$. Potential locations for stations are identified as local peaks and troughs and indicated in green.
Figure A.3: 95% Confidence Set for Parameter Estimates

Notes: 2008 Business Plan estimates. Pairwise projections of the 95% confidence set from column (6) in Table 5 in spherical normalization (see Appendix F.1). In blue are denoted all the points \((\vec{b}_k, \lambda)\) such that there exists a vector \((\vec{b}, \lambda)\) with \(b_k = b^*_k\) and \(b_l = b^*_l\) which belongs to the confidence set.

</table>

Notes: 2008 Business Plan estimates. Column (1) reports the distance in km between the optimal location and the proposed station. A positive number indicates a movement towards San Diego, negative towards San Francisco. Column (2) reports the change in aggregate welfare in basis points (%) given the Pareto weights $\lambda_U(i)$ between the optimal station placement minus the welfare corresponding to moving only the corresponding station back to its original location in the proposed plan. In columns (3)-(7), $\rho_X$ show the correlation between $\Delta \log \hat{W}(i)$ and the corresponding covariate $X$ in that one-deviation counterfactual from the proposed plan.
Figure A.5: Apolitical Planner, Robustness of Optimal Design

Notes: 2008 Business Plan estimates. Each panel displays how aggregate welfare is affected when moving the indicated individual station by about ±10km around the optimal location. Optimal stations are indicated in red, the proposed ones in black (sometimes outside).
